Since the completion of human genome project in 2003, a significant progress has been made in the field of human health and bioinformatics which was further fueled by the emergence of next generation sequencing (NGS) techniques. NGS has enabled quick analysis of huge number of samples with falling costs. This characteristic made it the most feasible and convincing method for studying uncultured gut microbial communities with no prior knowledge of the organism (Mandal *et al.*, 2015; Frey *et al.*, 2014). Gradually, this revolutionary technology resulted in development of new field of genomics called “metagenomics”, defined as direct genetic analysis of genomes present in particular ecology eliminating the need for cultivating clonal cultures. Based on the aim of study, metagenomics can be divided into (i) Marker gene amplification metagenomics or meta-genetics (Handelsman, 2009) which is used for identification and abundance analysis of bacterial community. It is primarily based on the diversity of one gene (e.g., 16S rRNA or functional genes like amoA/B, nirK, nirS and nosZ etc.) obtained after PCR amplification. (ii) Full shotgun metagenomics (Sun and Xia, 2015) which provides access to the functional gene composition of microbial communities giving much broader description than phylogenetic surveys.

(i) Marker gene amplification metagenomics

Since Woese and Fox (1977) first pioneered the use 16S rRNA gene in classifying microbes, it is regarded as the most versatile phylogenetic marker for microbial classification as (i) it is ubiquitous in bacteria (ii) its function is conserved over time and (iii) its length (~1500 bp) is appropriate for isolation, sequencing and subsequent bioinformatics analysis (Janda and Abbott, 2007). The 16S rRNA gene includes 9 hyper variable regions labeled as V1–V9 ranging from about 30–100 base pairs. Though, this gene is mostly conserved, the hyper variable regions can change in a very short evolutionary period and thus provides an advantageous and efficient way for microbe identification. Most 16S studies operate on one of these hyper variable regions at any given time due to technical constraints. Marker gene metagenomics is the preferable choice for diversity analysis as it targets specific region and thus, it is cost effective and computationally easy to analyze. However it restricts the

knowledge to only particular region studied, not providing any information of functional and metabolic aspects of microbial community present in the same.

(ii) *Full shotgun metagenomics*

As the word suggests, in full shotgun metagenomics, complete DNA including functional genes and phylogenetic markers are studied as a whole, thereby in addition to identification of microbes, it can provide information about the function of this microbial community. It is a perfect substitute to cumbersome cloning method requiring large amount of genomic DNA to sequence.

In the last decade, many studies have been carried out to analyze gut microbiota diversity using both the functional and phylogenetic approach using different NGS platforms. Metagenomics (DNA based) can be further combined with metatranscriptomics (mRNA based), metaproteomics (protein based) and metabolomics (metabolism based) to analyze composition, function, expressed activities to provide insights into bacteria-host interactions that may lead to disease (Wang *et al.*, 2015; Franzosa *et al.*, 2015). Currently five high throughput sequencing platforms are used for studying the gut microbiome diversity namely Illumina (e.g., GA II, HiSeq, MiSeq, NextSeq500), 454 Life Sciences Roche (GS FLX Titanium sequencer), Applied Biosystems SOLiD, life technologies' ion torrent personal genome machine (PGM) and Pacific Bioscience's (PacBio) Single-Molecule Real-Time (SMRT) (Medini *et al.*, 2008; Hodkinson and Grice, 2015). Out of these, Illumina is the choice of most of the researchers as it gives high throughput data and advantage of read length up to 300 bp. All these NGS technologies have already been reviewed pre-eminently by Mardis (2008) and Metzker (2010). The impact of different sequencing platforms for microbial analysis has also been reviewed and discussed in detail by Allali *et al.* (2017) and Clooney *et al.* (2016).

Bioinformatics Approaches to Study the Gut Microbiome

Computational tools, techniques and algorithms are frequently employed to understand and interpret biological data. The complexity and amount of data generated through latest sequencing technologies make it difficult to manually analyze and visualize data to extract meaningful results. Therefore, bioinformatics methodologies have been constantly evolving in various aspects and microbiome study is no exception. Broadly, bioinformatics approaches could be categorized into (i) Marker gene analysis (using a specific and ubiquitous gene across the microbial world, for e.g., 16S rRNA and ITS region) and (ii) Metagenomic analysis (Oulas *et al.*, 2015; Thomas *et al.*, 2012), as discussed briefly below:

Marker gene analysis (e.g., : rRNA or ITS region)

Popular bioinformatics tools employed for analysis of phylogenetic markers like rRNA amplicon and internal transcribed spacer (ITS) are MEGAN (Huson *et al.*, 2007), Mothur (Schloss *et al.*, 2009), MG-RAST (Glass *et al.*, 2010) and QIIME (Caporaso *et al.*, 2010). Among these, QIIME is the most widely used and established pipeline due to its continuous support and development, well written documentation and ease of use. Though, every tool has its unique core algorithm, there is a basic set of analysis steps (Fig. 3) which most of the tools use and is described below:

(1) *Pre-processing of sequencing data:*

Pre-processing includes trimming of sequencing reads according to quality, stitching the reads to generate longer stretches and removal of chimeras. FastQC (see "Relevant Websites section") and NGS Toolkit (Patel and Jain, 2012) are some of the most commonly used fastq quality assessment tools. After surveying the data, reads need to be trimmed for adapter sequences and filtered on the basis of quality or length as per experimental requirements. For this purpose, few tools like Cutadapt (Martin *et al.*, 2011), Trimmomatic (Bolger *et al.*, 2014) and FASTX Toolkit (see "Relevant Websites section") are frequently used. Some of the tools like NGS Toolkit and Trim Galore (Krueger, 2015) come with dual functionality performing quality assessment along with trimming, thus reducing an extra step. Studies suggest that longer sequence could capture much more information than the shorter ones which are typically 100–300 base pairs. Hence, paired reads could be stitched generating a single long stretch by exploiting the overlap between the paired reads. Several software are available to achieve the same including PEAR (Zhang *et al.*, 2013), FLASH (Magoč and Salzberg, 2011), bbmerge tool from BBMAP (Bushnell), PANDASeq (Masella *et al.*, 2012), COPE (Liu *et al.*, 2012a,b), UPARSE merge (Edgar, 2013) and fastq-join (Aronesty, 2011). All of them vary on the basis of sensitivity, performance and stitching percentage and could be used according to the experimental needs. Though, some of these tools may have high merging rate at default parameters, however, the rate of false positives may be high. Out of them, BBMerge has lower false positive rate than PEAR, FLASH and fastq-join. COPE is quite comparable or slightly better than FLASH in terms of overall performance, however, it is unstable at N=0. Following stitching, the subsequent pre-processing step is the removal of chimeric sequences which are PCR artifacts. Two or more biological DNA sequences may join incorrectly during PCR cycle to generate artificial novel sequence and may further lead to misinterpretation of data. For chimera identification, mainly two approaches are employed viz. reference based and de novo (absence of reference database having chimera free sequences). In case of reference based analysis, databases such as Gold (see "Relevant Websites section") and RDP (Maidak *et al.*, 1996) are generally used. However, de novo analysis is preferred method when no information is present for particular type of metagenome sample. Pintail (Ashelford *et al.*, 2005) and DECIPHER (see "Relevant Websites section") work using reference based approach and others such as USEARCH and UCHIME (Edgar, 2010; Edgar *et al.*, 2011), ChimeraSlayer (Haas *et al.*, 2011) and Perseus (Quince *et al.*, 2011) can work either way. The advantage of UCHIME is that it works equally well with both ITS sequences and 16S

Fig. 3 Bioinformatics workflow for 16S rRNA marker gene studies. The analysis starts from pre-processing of raw sequencing reads followed by clustering and OTU picking with suitable strategies. Taxonomy is assigned by alignment methods and generating phylogenetic tree to draw evolutionary relationships. Diversity analysis (alpha and beta) is useful to study inter and intra sample diversity.

amplicon. It is also the default method when USEARCH is used in QIIME (Navas-Molina *et al.*, 2013). Chimera identification is a crucial step and the tool to remove it should be carefully chosen.

(2) Clustering and OTU picking

The word OTU stands for Operational Taxonomic Unit and there are different views on the origin and the exact meaning of the same which is out of the scope of this discussion. However, in context to metagenomics, OTU can represent an individual organism, a named taxonomic group i.e. species or genus, or a group with undetermined evolutionary relationships sharing common characters. Hence, it is often up to a scientist to put a proper context to OTU with the study. Generally, gut samples are obtained in batches and hence are often multiplexed. Such samples are first de-multiplexed (reads are assigned to samples based on unique barcode attached to the sequences) followed by OTU picking step which is basically clustering of similar sequences at (typically) 97% identity or more. However, the identity threshold of 97% may be considered for revision taking into account the increased number of high quality 16S sequences till date (Edgar, 2017).

Sequences thus clustered are considered to represent the same bacterial species (Janda and Abbott, 2007). Methods for OTU picking may vary widely and the most commonly used tool QIIME supports three different approaches, viz (i) de novo, (ii) open reference and (iii) closed reference, all of them uses UCLUST as default algorithm. As the name suggests, denovo method is solely based on pair wise identity among sequences in the absence of a reference dataset. While open and closed

reference methods relies on reference dataset for OTU picking. But the primary difference between them is, in case of open reference method the sequences are clustered based on hits obtained against reference dataset followed by denovo clustering of reference unaligned reads, whereas in case of closed reference method, reads after alignment to reference database are discarded. When a little is known about sample, the best approach is to select is open reference method as it takes advantage of reference as well as denovo method, thereby giving an adequate chance for identification of novel species. The next step is to pick representative sequence of each OTU generated, so as to reduce the time and resources in further downstream analysis. Again, different strategies are employed for picking up the representative sequence. The longest or the first or the most abundant sequence could be picked up as a representative.

(3) *Taxonomic assignment of OTUs and alignment*

Given a set of sequences and reference dataset, in the next step, taxonomy, associated with the reference sequences, can be assigned to each sequence using a variety of algorithms. There are a number of rRNA sequence databases containing well annotated and curated sequences of bacterial/archaeal and fungal origin. Some of the widely used rRNA databases include RDP (Maidak *et al.*, 1996), SILVA (Pruesse *et al.*, 2007), GreenGenes (DeSantis *et al.*, 2006a) and EzTaxon-e (Kim *et al.*, 2012). However, reference databases for ITS data analysis are quite few; most widely accepted being Unite (Kõljalg *et al.*, 2005). A number of different algorithms are available in QIIME itself, such as uclust (Edgar, 2010), BLAST (Altschul *et al.*, 1997), RDP classifier (Wang *et al.*, 2007), Mothur (Schloss *et al.*, 2009) and tax2tree (McDonald *et al.*, 2012) which can be employed to search for the best possible match for an OTU in reference database assisting in inferring the possible taxonomic lineage. However, RDP classifier has an added advantage of providing bootstrap confidence score along with the taxonomy assignment (Lan *et al.*, 2012). Higher the score, higher is the confidence that read belongs to a particular reference lineage. A threshold of 0.8 is used as default bootstrap confidence score in QIIME (Navas-Molina *et al.*, 2013).

In addition to taxonomic assignment, it is important to represent evolutionary distance between the sequences in form of phylogenetic tree wherein the distance can be visualized in FigTree (Rambaut, 2009) or TreeView X (Page, 2002) software. Result of multiple sequence alignment is used as an input for phylogenetic analysis which in turn can be obtained using tools like clustalW2 (McWilliam *et al.*, 2013). However, a more recent method to achieve the same is to use NAST algorithm (DeSantis *et al.*, 2006b) to align the OTU representative sequences to a pre-aligned reference database of 16S sequences (often called a “template”). For instance, QIIME uses PyNAST (Caporaso *et al.*, 2009) which is a Python implementation of the NAST. Another tool called Infernal makes use of an HMM approach to incorporate secondary structure information. Due to incorporation of secondary structure information, it is better at identifying variable rRNAs sequences conserved at structural level though, it is a bit slower.

(4) *Diversity analysis:*

The basic components to estimate the microbial diversity are alpha, beta and gamma diversity. Within sample diversity is represented by of alpha diversity which is indicative of “richness” (total number of species in the sample) and “evenness” (distribution of relative abundance of species). To remove the bias introduced by sequencing depth while capturing the true diversity, rarefaction curves are often drawn to determine whether the sequencing depth is adequate to represent the total diversity within the sample. Several metrics are available in both Mothur and QIIME to calculate alpha diversity. The metrics are broadly divided into 2 categories, viz. phylogenetic and non-phylogenetic, depending upon their ability to utilize phylogenetic information of microbes. Shannon index, Simpson’s index, Good’s coverage, chao1, observed species are non-phylogenetic bases metrics. Chao1 and observed OTUs/species metrics are used to get total diversity in sample, while metrics like Shannon index and Simpson index are used to get information on relative abundance of each taxon identified as well as diversity captured found in sample. On the other hand, phylogenetic diversity metric like Phylogenetic diversity (PD) whole tree takes phylogeny of microbes into account to provide diversity in the sample. Thus it has the added advantage of providing divergence-based analysis (Lozupone and Knight, 2008) for sequences which are different in base composition but similar at metabolite level.

Beta diversity is a term for the inter-sample comparison or across environmental sample comparison which is estimated by calculating the distance between samples using popular metrics like Unifrac (Weighted and UnWeighted), Bray-Curtis, Euclidean and Abundance-Jaccard. Like alpha diversity, beta diversity can also be divided as phylogenetic and non-phylogenetic based methods. Metric such as Jaccard provides richness estimation and Bray-Curtis, Euclidean can provide richness as well as evenness estimation among samples thereby giving better idea about the differences shared by different samples. However, Unifrac metrics like Unweighted and Weighted are phylogenetic based metrics for qualitative as well as quantitative beta diversity analysis respectively (Lozupone and Knight, 2008). Gamma diversity provides the total species diversity found across all samples.

(5) *Statistical analysis and visualization:*

The final step in broad characterization of complex microbial population is correlating gut microbiome with diseased or normal metabolic profile in human using different statistics and visual aids. MG-RAST (Glass *et al.*, 2010) performs a comprehensive analysis and at the end provides a detailed report which is publication ready. Similarly QIIME provides python based programs for 3D visualization of the correlation between the samples using principal coordinates analysis (PcoA). Further, procrustes analysis (Gower, 1975) is often performed to compare weighted and unweighted UniFrac PCoA plots generated by the same processing pipeline adding another dimension. PICRUSt (Langille *et al.*, 2013) analysis could also be carried out to derive functional aspect of sample using 16s rRNA gene information. The visualizations and further statistical tests are not limited to the popularly available tools. There are in fact, a number of open sources and commercial tools/programs/packages like R, SAS and MATLAB available to extend the understanding. Finally, programming in high level languages like Python cannot be ignored and

in fact the complete QIIME pipeline is being written in Python. Advanced, Python packages like NumPy and SciPy are often used parallel.

Metagenomic analysis

(1) Metagenomic assembly:

Unlike, marker gene study involving analysis of specific region of genome, metagenomics is study of complete set of genomes from a cohort of microbes within an environmental sample. Though the third generation sequencing techniques (PacBio and Oxford Nanopore) have come up with longer reads, the assembly of overlapping reads into continuous or semi-continuous genome fragments also known as contigs or scaffolds is essential. Assembly of the reads allows an exhaustive analysis by reliably assigning specific functions or taxa as compared to gene fragments or unassembled reads. This step can be accomplished using any of the two approaches viz. *de novo* or reference based/guided. While a reference based approach is suitable in the presence of already sequenced reference genome to be used as a road map for genome reconstruction, a *de novo* assembly is preferred in the absence of the same. Assemblers are further categorized based on the type of algorithm they implement (i) de-bruijn graph based & (ii) Overlap Consensus Layout (OLC) (Li *et al.*, 2012). De-bruijn graph works by dividing reads into subsequences (kmers), making it appropriate approach for short reads. While, OLC works best with long reads (>300 bp). Tools such as Newbler (Chaisson and Pevzner, 2008), MIRA (Chevreux *et al.*, 1999) or are mostly employed for performing referenced based assemblies. Traditionally, for *de novo* assembly, assemblers such as SOAPdenovo2 (Luo *et al.*, 2012), SPAdes (Bankevich *et al.*, 2012), Velvet (Zerbino and Birney, 2008) and commercial tool like CLC genomics workbench are popularly used. However, for metagenomic samples, assembly poses challenges due to various reasons. Relative abundance of microorganisms in a sample is not always even, which results in some genomes being sequenced at a greater depth and coverage as compared to the rest. This problem usually boils down to either misassembling of metagenome or entirely missing out the less abundant species. This scenario worsens when sample contains microbes of related strain sharing most of their genomic content. Another challenge for metagenomic assembly is the computational constraint that is inherent with the diversity of microbes (Howe and Chain, 2015). To tackle these problems, the improved class of assembly tools, such as metaSPAdes (Nurk *et al.*, 2017), MEGAHIT v1.0 (Li *et al.*, 2016), IDBA-UD (Peng *et al.*, 2012), MetaVelvet (Namiki *et al.*, 2012), Meta Ray (Boisvert *et al.*, 2012) and Omega (Haider *et al.*, 2014) were developed. Recently developed tool, metaSPAdes address all these issues and provides competent result capturing low abundance microbes but, it cannot handle multiple libraries at a time. Whereas IDBA-UD takes uncompressed fasta files as input and doesn't support fastq format which is most common output from the latest NGS platforms. Similar is the issue with Omega which accepts uncompressed fasta and fastq format, but neither supports its compressed version nor aid with multithreading. On the other hand, Omega works on OLC approach preferred by researchers working with long reads. Few tools like Metavelvet and Megahit, are required to specify maximum kmer to support during or before source code compilation. Assembler results vary greatly depending upon the sample and its microbe content (simple or complex). However, recent study by Vollmers *et al.* (2017) shows that tools like IDBA-UD, Megahit and metaSPAdes employing multi kmer approach provide better results in terms of diversity captured when dealing with sample having high complexity. Still, metagenome assembly has scope for improvements in terms of computational performance and accuracy of assembling reads.

(2) Binning

Some of the most common challenges to metagenomic assembly are the uneven coverage across the sample, errors introduced during sequencing and stretches of repeated sequences (Brubach *et al.*, 2017). Hence, another approach called "binning" has been introduced which essentially means to group reads or contigs into so called "bins" and assigning them to operational taxonomic units (OTUs). The primary objective of binning is to group together the fragments belonging to same organism based on information such as sequence similarity, sequence composition or read coverage (Dröge and McHardy, 2012). Clustering and data representation are the two components of binning; where clustering involves bringing together the fragments like contigs or scaffolds followed by grouping these clusters with data representation approaches into taxonomic bins (Sangwan *et al.*, 2016). This approach is considered better for capturing novel microbes in the sample. However, precision of binning highly depends upon the quality of metagenome assembly. According to the availability of pre-existing bins derived from the genomics sequences, the binning algorithms are further classified into (i) supervised binning, when bins are already available & (ii) unsupervised binning, when no pre-existing bins are available. There are a number of tools and pipeline that implements binning process such as MG-RAST (Glass *et al.*, 2010), TACAO (Diaz *et al.*, 2009), MetaPhyler (Liu *et al.*, 2010), PhyloPythia (Patil *et al.*, 2012), SOrt-ITEMS (Monzoorul Haque *et al.*, 2009), IMG/M (Markowitz *et al.*, 2013), CARMA3 (Gerlach and Stoye, 2011), S-GSOM (Chan *et al.*, 2008), MEGAN (Huson *et al.*, 2007) and PhymmBL (Brady and Salzberg, 2009) etc. Use of long reads generated from 3rd generation sequencing platform like Pacbio RS II for metagenome analysis can result in improvement of assembly which in turn can help achieving accurate binning and taxonomy assignment (Frank *et al.*, 2016). Tools like CARMA3 and PhymmBL uses combination of two approaches for the process of binning from which one is BLAST, thus it provides added advantage in taxonomic classification (Teeling and Glöckner, 2012).

(3) Annotation:

One of the most important steps in gut microbiome study is the identification and subsequent annotation of the coding regions within the metagenome. A number of tools are available for gene identification such as MetaGeneMark (Zhu *et al.*,

2010a,b), Prodigal (Hyatt *et al.*, 2010) and Metagene (Noguchi *et al.*, 2006). Another tool called FragGeneScan (Rho *et al.*, 2010) has been implemented in MG/RAST and IMG-ER which is considered better as compared to Metagene because it can handle sequencing error introduced by NGS technology. Additionally, it can work at read as well as assembly level. Non-coding RNAs such as tRNAs are commonly identified using the tools like tRNA-Scan (Lowe and Eddy, 1997). However, rRNAs can be predicted by comparing sequences to curated rRNA sequence database like Greengenes, SILVA and RDP. Functional annotation is performed by aligning the coding sequences against reference databases to perform homology searches usually with BLAST program. A recently developed alternative for blastx/blastp is Diamond (Buchfink *et al.*, 2015) which is 20,000 times faster than BLAST and is very often used for larger datasets. Of course, high performance computing clusters or commercial cloud computing services like Amazon EC2 (Walker, 2008) have significantly speeded up the time taken to perform these tasks. In the list of standalone programs, COGNIZER (Bose *et al.*, 2015) is an impressive addition since it enables direct derivation of KEGG, Pfam and GO from COG categorizations. Additionally clustered regularly interspaced short palindromic repeats (CRISPRs), a regulatory element can also be identified using specific tools like CRISPR recognition tool (CRT) (Bland *et al.*, 2007). The main limitation of most of these annotation tools is that they assume metagenome data to contain more of bacterias and archeas and thus eukaryotes like fungus having complex genomic structure interspersed with intron are ignored to some extent.

Case Study: A Core Gut Microbiome in Obese and Lean Twins

As represented by Mandal *et al.* (2015), many publications have demonstrated the association of gut microbes with obesity as compared to other diseases. Thus, here we present a case study carried out by Turnbaugh *et al.*, in 2008 considering obese and lean twins to show the effect of gut microbiota on obesity/leanness. Two set of individuals were examined in this study (i) 154 individuals (31 monozygotic twin pairs, 23 dizygotic twin pairs and 46 samples of their mothers (if available) at two time points and (ii) 18 individuals (3 lean and 3 obese European ancestry monozygotic twin pairs along with their mothers). Monozygotic, dizygotic co-twins and parent-offspring pairs were examined for research as they provide an appealing model for determining the core gut microbes and influence of genotype and shared environment on microbe composition.

Molecular technique and sequencing:

Set (i) of 154 individual samples: 16S rRNA sequencing approach using ABI 3730xl capillary sequencer as well as 16S rRNA V2 variable region13 and V6 hypervariable region1 using Roche 454 FLX instrument.

Set (ii) of 18 individual samples: Shotgun pyrosequencing using Roche 454 FLX/Titanium.

Findings:

- Not a single phylotype was found among all the sample whose abundance was more than 0.5%.
- Samples taken from the same individual at different time point's subsequently exhibited stable phylotypes. However variation was witness in relative abundance of the principal gut bacterial phyla.
- Obesity was marked by notable decrease in the level of diversity. Besides lower proportion of Bacteroidetes and a higher proportion of Actinobacteria in obese compared with lean individuals of both ancestries.
- High level of similarity at functional metabolic level was observed in contrary to excessive diversity concerning relative abundance of bacterial phylum.

This study revealed that, rather than at the phylotype level, the core gut microbiome prevail at the level of shared genes and metabolites.

Application of Gut Microbiome in Healthcare and Medicine

With the increased incidence of use/misuse of antibiotics as a treatment for different diseases, some major health issues have been raised. It is well established fact that bacteria are gradually developing resistance against many antibiotics. In Salyers *et al.* (2004) revealed that gut microbiota may act as a reservoir of antibiotic resistance when antibiotics pass through the colon. Widely used broad spectrum antibiotics as a side effect kills commensal and 'beneficial bacteria' along with pathogens thus influencing complete microbial community in gut (Shetty *et al.*, 2013). In adults, disruption of gut microbes may lead to pathogenic infection (Robinson and Young, 2010). Antibiotic like ciprofloxacin, when used in excess can lead to reduction in diversity and evenness of bacterial community in gut (Dethlefsen *et al.*, 2008). Hence knowing the fact that antibiotics can derange the protective microbes and increase susceptibility to infection, highlighted the importance of so called 'microbial interference treatment' (Bengmark, 1998). In last decades, our insight of gut microbes and their role in health and pathophysiology has refined a lot. With increased research, it is known that some disease condition can even be treated or improved using specific types of bacteria as a food component or supplement known as "probiotics" (AFRC, 1989). This term is derived from the Greek word 'biotikos' meaning 'for life' i.e., it is used to denote microbes that upon ingestion in requisite amount promotes well being beyond those of inherent fundamental nutrition, boosting gastrointestinal (GI) system (Conly and Johnston, 2004). They are likely to show positive impact upon a range of acute and chronic pathologies (Table 1). The health

Table 1 Diseases and their associated bacteria.

Disease	Name of prevalent bacteria	Reference	Probiotics
Type 2 diabetes	Akkermansia muciniphila	Qin <i>et al.</i> (2012)	Lactobacillus acidophilus, Lactobacillus rhamnosus, Lactobacillus casei, Bacillus longum, Bacillus breve, Lactobacillus sporogenes (Zhang, Q., Wu, Y. and Fei, X., 2016)

benefits of these bacteria are strain specific and thus even a change of strain can affect the outcome (Guarner and Malagelada, 2003). The evidence that, probiotics can be used as effective treatment came after studying patients suffering from diarrhoea. It was observed that in case of acute gastroenteritis in children, the use of either *Lactobacillus rhamnosus* or *Lactobacillus reuteri*, or *Lactobacillus casei* significantly decreased the duration of diarrhoea (Raza *et al.*, 1995; Shornikova *et al.*, 1997; Pedone *et al.*, 1999). It is assumed that diet induced obesity might also be reversed with use of specific diet or by manipulation of gut microbiota by mean of probiotics. Ait-belgnaoui *et al.* (2009) have shown that *Lactobacillus farciminis* taken as a probiotics can affect spinal neuronal activation. Supply of specific lactobacillus along with oat fiber was observed to significantly lower infections associated with pancreatitis, liver transplants and abdominal surgery (Rayes *et al.*, 2005; Rayes, 2004; Olah *et al.*, 2002). Consequently, probiotics can either be used as a replacement or to augment antibiotic effect to re-impose and promote the beneficial microbes in our bodies against diseases condition (Reid, 2006). Deciphering all these advantageous effects, probiotics can be considered as important part of overall care of the patient. Therefore, the study of gut microbiome in different population is vital to apprehend the mechanisms of action and basal of our microbiota for the development of indigenous probiotic strains to be further used for improvement of disease condition.

Gibson and Roberfroid (1995), first introduced the term “prebiotic” explained as nondigestible food ingredient when ingested in body promotes host well-being by nourishing the growth and/or activity of one or a confined number of bacteria in the colon. Prebiotics may include oligosaccharides (like oligofructose, galacto-oligosaccharides) peptides and lipids which could alter endogenous biochemical pathways, by remodeling the specific intestinal microbial communities residing in the colon (Versalovic and Wilson, 2008). List of prebiotics may extend to use of some type resistant starches and sugar alcohols. They may work by blocking the pathogen binding and providing nutrients to useful gut microbes. To infer the mechanism of working of prebiotics, altered activities can be evaluated by structural to functional studies using metagenomics, metaproteomics and metabolomics approach. It was observed that, when transgalactosylated disaccharides was used as a prebiotics, there was increase in number of Bifidobacteria and Lactobacillus whereas decrease in Bacteroides sp. and Candida sp. (Ito *et al.*, 1993). Only side effect of use of prebiotics is increased gas production. However when dealing with prebiotics one need to focus more on understanding its sufficiency, gut passage time and osmotic regularity. Similar to probiotics, studies to determine effective dosage and duration of probiotic exposure showing its effect is necessitate (Reid *et al.*, 2003).

When combination of probiotics with prebiotics is used together for management of microflora, they are known as synbiotics which exemplifies synergism. Theoretically, if prebiotics are taken together with suited probiotics, they may boost the activity of probiotics and their survival along with GI inhabitant microbiota. It is known that synbiotics elevate the number of balanced gut microbiota and also improve immunomodulating ability (Zhang *et al.*, 2010).

However, currently the process of Fecal Microbiota Transplantation (FMT) is in trend. It implicates transplantation of fecal microbiont from healthy individual to recipient in order to refurbish healthy microbiota community and thus deliberate its health benefits (Bakken *et al.*, 2011; Smits *et al.*, 2013). Although FMT was first introduced in year 1958 by Eiseman *et al.* for the treatment of pseudomembranous colitis (Eiseman *et al.*, 1958), but recently it received attention when it offered promising solution against recurring *Clostridium difficile* infection (Smits *et al.*, 2013; Bakken *et al.*, 2011). Due to some trepidations associated with FMT like patient acceptance, infectious potential and treatment standardization, its use is restricted only in case of failure of traditional therapies (Ji and Nielsen, 2015). Being natural and considerably economical treatment, it is favorable to use (Kelly *et al.*, 2015). It is anticipated that in near future, FMT may come-up as a fruitful treatment for other conditions like IBD, obesity, metabolic syndrome and functional gastrointestinal disorders (Gupta *et al.*, 2016).

Future of Gut Microbiome Research

Following the discussion so far, it is evident that studying the gut microbiome has significantly changed our views on how we associate health conditions with their root causes (Zhang *et al.*, 2015). The deeper we have dug into it, the better we have understood the striking correlations of gut microbiota with chronic (Guinane and Cotter, 2013) as well as acute disorders (Shukla *et al.*, 2017). With a detailed understanding of the human microbiome landscape, the possibility of synthetic microbiome modulating the health should not come as a surprise (Waldor *et al.*, 2015). New attempts have already been taken for microbiome replacement therapies, both from natural (Vrieze *et al.*, 2012) and synthetic source (Petrof *et al.*, 2013) with promising results. However, further research is of course required for it to become a routine medical practice and overcoming the inherent limitations. Researchers are further narrowing down stool microbiota ensemble to scientifically validated set of beneficial or rather remedial microorganisms which may be a paradigm shift in medical practices. A recent UNICEF survey (Source: UNICEF/WHO/World Bank Joint Child Malnutrition Estimates, May 2017 edition) suggests that nearly half of all deaths in children under 5 years attributes to under nutrition which translates into the unnecessary loss of about 3 million young lives a year. One can imagine the outcome of such studies to repair the defective gut of such undernourished children along with the food restoring health. Finally, we may also redefine the formal definition of the food we consume by essentially adding the details of gut microbiome associations. With all that said, there are certain aspects which need to be thoroughly considered while drawing conclusions. Firstly, gut studies are mostly carried out by fecal sampling which only represents the luminal microbiota which considerably differs from the mucosa-associated microbiota. Secondly, it is very crucial for viral and fungal species to be taken into consideration along

with the bacterial species while studying the gut microbiome. And finally, a large numbers of varying human populations needs to be considered for sampling to establish microbiome-health relationships using combination of techniques to screen transcripts, proteins and metabolites along with the genomic sequences. On the technical side, there is a need for fast paced high performance yet sensitive bioinformatics tools to capture the information as efficiently as possible. The good news is that bioinformatics tools and methods to analyze the microbiome data are evolving in parallel with next generation wet-lab techniques to extract required samples. Hence, there is no doubt that computational techniques will continue to play a major role in the extraction of meaningful information from constantly piling up data.

Closing Remarks

With a number of human gut profiling studies being carried out, it is evident that microbes present in GI has major role to play in human well-being and disease condition. A large number of collaborative projects have been initiated to dig deeper into the understanding of function of these microbes and how their composition is impacted by diet, age, environment etc. Advancement of sequencing methodology, dropping sequencing cost and availability of easy to use bioinformatics tools has encouraged analysis of large number of gut metagenome samples simultaneously. Phylogenetic marker gene studies using next generation sequencing are routinely undertaken as a first choice to get taxonomy profile of a gut sample, answering basic question “who is there”. But owing to the limitation of 16S rDNA gene study to answer some of the crucial question like ‘how they function’ and ‘how they interact with gut ecosystem’, approaches including whole metagenome, metatranscriptome, metaproteome and metabolomic are required. Thus to get a bigger and clear picture of overall activities of microbes and their involvement in human health, it is necessary to understand which genes are expressed and which metabolites are produced by particular microbe community. Advance bioinformatics analysis and statistical tools and software have made it possible to decode biological information from large number of samples to understand mechanism and mode of action of these microbes. With the ever increasing amount of data generation for gut profiling, certain limitations and issues of existing tools need to be overcome to meet the ever increasing demand. More and more information collected for these microbes is also helping to extend the dimension of their potential and use in health care industries. Thereby, it has given a strong hint that gut microbes study cannot be ignored while moving towards the era of personalized medicine.

Acknowledgment

We would like to thank Xcelris Labs Ltd., Ahmedabad, India for providing the resources and support. We would also like to thank the bioinformatics team at Xcelris Labs for their constant support and motivation.

Biographical Sketch

Toral Manvar is a registered doctorate student at Gujarat University, Ahmedabad, India. She has more than 7 years of experience in CRO research and bioinformatics. She is working as team leader in NGS bioinformatics division at Xcelris Labs Ltd., Gujarat, India. She has completed her Master's in Bioinformatics in 2009 from Sardar Patel University, V.V Nagar, Gujarat, India. She has special interest in Next Generation Sequencing data analysis involving different DNA and RNA based applications and particularly metagenomics. She has experience in teaching and is currently involved in mentoring and tutoring bioinformatics to graduate and undergraduate students.

Vijay Lakhujani is a certified bioinformatician (Dept. of Biotechnology, Govt. Of India) with deep interest in Genomics and next generation sequencing technologies. He has 6.5+ years of industry experience working on design, implementation and analysis of microarray data and high-throughput NGS data. He is working as Project Scientist in NGS bioinformatics division at Xcelris Labs Ltd., Gujarat, India. He has completed his Masters in Bioinformatics in 2011 from University Of Pune, Maharashtra, India. He has special interest in computational process automation, programming and visualization. He has been formally certified as "lecturer" (CSIR-NET-JRF + LS, Govt. of India) and is involved in providing bioinformatics knowledge sharing sessions and bioinformatics trainings to graduate and undergraduate students.

Introduction

Biological systems are complex entities with several levels of complexity inter-linked and integrated to perform diverse tasks which are monitored and coordinated closely by complex regulatory systems. The organismal level dynamics are result of complex interactions between network of genes, proteins and other biological macro and micro-molecules. These interactions across different omic levels regulate the organism's form and functions and any rewiring leads to disruption of the entire system leading to different disorders depending upon the nature of change. A comprehensive understanding of the different regulatory systems including genomics, proteomics, and metabolomics coupled with the integration of this information into a unified model will lead to better understanding of the resultant phenome at an organismal level. Hence, it is increasingly evident that a systems approach is needed to gain a deeper insight into any biological state of interest. A holistic systems approach allows us to integrate the information collected from different omic studies in order to visualize and understand the complete landscape at the organismal level (Rhee *et al.*, 2008).

Systems level probing is now possible owing to the tremendous technological advances in high throughput experimentation. Studies yielding complex proteomic and genomic datasets help us gain insight into the dynamic changes in the landscape including differential expression and activation of specific pathways depending on the biological situation. The cost of these high throughput omic or multi-omic studies has also fallen dramatically over recent years, making them increasingly affordable and sensitive. This has resulted in a huge deluge of data generated from these high throughput omic studies being performed by investigators who are increasingly motivated to gain systems-level insights into their experimental systems. While generating omic data has become far easier, the difficulty in interpreting the results of such experiments has risen dramatically with the size of datasets, at times proving to be overwhelming for unexperienced researchers.

The analysis of any high throughput experiment ultimately converges upon the identification of all any significantly dysregulated molecules (e.g., genes, proteins, etc.) which are speculated to serve as possible leads that may shed light on the cellular dynamics in the particular biological context of experimental interest. A common analytical approach often hinges on studying differentially expressed genes to identify biomarkers or unique signatures that characterize a specific phenotype. Understanding how individual biomolecules influence a specific phenotype can be invaluable in the advancement of scientific understanding, but understanding the complex interactions and cumulative effects of all biomolecules present within a given system can be just as important despite being a more difficult analytical task. Manual annotation and examination of the roles of each of the dysregulated molecules along with interpretation of their collective roles in a given system is very tedious and time-consuming. It requires thorough study of both extant literature and available databases in order to gather information regarding the functional roles of all the molecules of interest (Hill *et al.*, 2010; Hoehndorf *et al.*, 2015).

Establishing the functional roles of each of the molecules of interest in a particular experimental context is essential in order to draw any conclusions or inferences from the data. When attempting to identify molecules of interest in a complex high throughput dataset, a functional enrichment analysis is the most commonly used approach for analysis and interpretation of biological. Functional enrichment analysis is possible due to the development of unified biological ontologies by the Gene Ontology (GO) Consortium which remains same across eukaryotes. The aim of the Gene Ontology Consortium was to develop, maintain and update well structured, precisely defined terms – also known as ontologies – that articulate the roles of biological molecules across different species (Gene Ontology Consortium, 2015). The GO Consortium is discussed in detail later in the article.

Functional enrichment analysis using the GO database was rendered possible by the emergence of bioinformatics tools that can retrieve information from the GO database. With the advent of these tools it became possible to summarize the information regarding all biological activities in which a particular molecule is known to participate. This information can then be condensed into a succinct

enrichment summary. This analysis involves the use of a statistical approach to investigate abundantly represented classes of biological macromolecules such as genes, proteins or metabolites actively involved in different biological processes, molecular functions and cellular compartments. This approach allows us to generate a more holistic view of an experimental system, letting us visualize the biological roles of the differentially expressed biological macromolecules and deduce the significantly enriched biological themes. The different enrichment techniques used by different tools to assess enrichment are described below.

Types of Enrichment

There are three algorithms for performing enrichment analysis: Singular enrichment analysis (SEA), Gene set enrichment analysis (GSEA), Modular enrichment analysis (MEA) (Tipney and Hunter, 2010).

SEA

SEA is a relatively simple, easy-to-use approach to enrichment that is the most traditionally utilized. An SEA analysis takes a list of genes with particular values (e.g., Fold-change values) as the inputs and iteratively procures the associated annotation terms from the GO database for each of these genes. This approach estimates a p-value for each of the retrieved annotation terms by comparing the observed frequency of a term with the frequency expected by random chance. All the terms beyond a threshold (usually p-value ≤ 0.05) are considered to be significantly enriched. Statistical tests that are used to facilitate the identification of significantly enriched GO terms include the Chi-square test, Fischer's Exact Test, Binomial Probability or Hypergeometric distribution. A more detailed discussion of the different statistical methods used for enrichment analyses can be found in the later sections of this article. Once compiled, each of the significantly enriched annotation terms associated with each of the genes in the input gene list are then listed in form of a table. One caveat to this approach is that it ignores the hierarchical relationships between the annotation terms, and it can thus lead to redundancy within the enriched terms owing to association of multiple terms with a single biological process. Some of the tools that use this approach are: Onto-Express, FuncAssociate 2.0 and BiNGO (Berriz *et al.*, 2009; Draghici *et al.*, 2003; Maere *et al.*, 2005).

GSEA

The GSEA approach is best-suited to a comparison-based analysis between two classes of data, multiple scenarios of data points or a single dataset across a series of timepoints. This approach requires a biological metric (e.g., Fold-change or expression) for each biomolecule of interest in order to rank them. A maximum enrichment score (MES) for all genes in a particular category is generated as an output of the GSEA analysis. Once MES scores are compiled, a p-valuebased assessment is done by comparing the ranked MES to the randomly generated MES distributions to assess for enrichment for particular terms beyond what would be expected due to chance. Unlike SEA, GSEA analyses determine whether the ranked list of genes share a particular annotation and form gene sets, reducing the redundancy that can arise from similar GO terms in SEA analyses.

Tools such as GSEA/P-GSEA, GeneTrail use this approach for enrichment analysis (Keller *et al.*, 2008; Mootha *et al.*, 2003; Stöckel *et al.*, 2016; Subramanian *et al.*, 2005).

Modular Enrichment Analysis (MEA)

The MEA approach considers the relationships between the different annotation terms during enrichment. Thus, this approach has better sensitivity and specificity owing to the reduction in the redundancy inherent in SEA/GSEA analyses. This modular approach allows the analysis software to deduce the biological theme in a much more refined manner as it considers the relationship between the terms, rather than just processing individual terms in the two above mentioned processes. Tools such as Ontologizer and GeneCodis use this approach (Bauer *et al.*, 2008; Carmona-Saez *et al.*, 2007).

Steps for Enrichment Analysis

Functional enrichment analysis can be performed using a range of tools that make use of different enrichment strategies. While the details of each protocol differ, these tools share common basic principles that are outlined below.

The starting point of any enrichment analysis is the generation of raw input data to be analyzed in the form of a list of biomolecules. Depending on the nature of study, enrichment analysis can be performed using lists of genes, proteins or metabolites. The list of molecules used can be ranked or unranked depending upon the enrichment algorithm employed by the tool. The tool to be used also should be selected carefully on the basis of the expected results from the analysis (Yang *et al.*, 2008).

Step 1: Calculation of Enrichment Score

The selection of genes to be used for downstream analysis using any tool and algorithm needs to be carefully compiled, as the entire functional analysis will be based on this list. The choice of using a ranked or unranked list depends upon the desired outcome expected

and the tool being used for analysis. To ensure that meaningful and specific results can be obtained, a background dataset should be included in the analyses. This background dataset is the list of all the molecules identified in the study, including the significantly dysregulated or important as well as the identified molecules of interest. The background database serves to improve the accuracy of the enrichment score and nullify any biases introduced in capturing the molecules due to experimental procedures.

Once this gene list has been generated and provided to the analysis software, ontology terms for each molecule are fetched from the GO database. These terms encompass a range of molecule descriptors including their functions, the processes/pathways in which they participate or the cellular compartments where they are localized. Ontology terms for the query and background lists are compared to assess the enrichment of different terms and processes. The enriched processes/pathways are those that are overrepresented in the query dataset relative to the background dataset. The enrichment score is a quantified value for each of the ontology term found to be associated by the query molecules.

Step 2: Estimation of Enrichment Score Significance

The statistical significance of the enrichment score can be calculated by using Binomial, Fischer's exact, Hypergeometric or Chi-square tests. The Binomial probability is used when the list of background molecules is large. The Fischer exact, Chi-square and Hypergeometric distributions are better suited to analyses with smaller background datasets. The statistical significance of the enrichment score is quantified with the help of a p-value denoting the extent to which the occurrence of the enrichment of a term is likely to be due to random chance. All terms below a chosen p-value threshold, typically 0.05 (representing a 5% chance of a given enrichment being due to chance), are considered to be significantly enriched. For a more stringent analysis, the p-value threshold can be further decreased to 0.01 or lesser. Many tools also implement alternative mathematical approaches. The user should decide the best suitable statistical method for the dataset.

Step 3: Adjustment for Multiple Hypothesis Testing

As multiple comparisons are being made simultaneously, adjusting p-values to account for false discovery rate (FDR) is necessary in enrichment analyses. FDR is used to control the family-wise error rate, and, an FDR threshold of 1% allows only 1% of the values to be observed by chance when drawn according to the null hypothesis. To account for this FDR, multiple hypothesis correction is applied to the results of the above statistical analysis. The majority of functional enrichment analysis tools perform such corrections using Bonferroni, Benjamini-Hochberg and also Holm, Q-value, and Permutation correction algorithms (de Leeuw *et al.*, 2016).

Gene Ontology Consortium

The Gene Ontology Consortium ("see Relevant Websites section") was developed to provide a comprehensive resource for functional enrichment analysis. It is a collaborative effort that annotates biological macromolecules on the basis of experimental evidence to describe their different biological roles.

GO annotations describes the molecular functions contributing to different biological processes and cellular compartments where these occur. It also includes references to the experimental evidence supporting these associations. The GO consortium has painstakingly addressed the constant need for the development, maintenance and improvement of consistent annotations across species. This group has successfully compiled functional information from over 460,000 species including plants, animals and microorganisms (Gene Ontology Consortium, 2015).

Several commercial and open-source tools have been developed to facilitate quicker functional enrichment analyses, allowing researchers to probe the complexity of their large datasets. In the following sections we describe several tools which can be used for such analysis. Table 1 provides the list of widely used tools for functional enrichment.

DAVID

The Database for Annotation, Visualization and Integration Discovery (DAVID) was released in 2003 with the aim of providing users with a simple user interface for quick biological interpretation of large datasets. The DAVID knowledgebase integrates a broad range of publically available annotation resources in a centralized location, thus enhancing the quality of high-throughput functional annotation analysis. The entire DAVID is freely available for download in simple text format ("see Relevant Websites section") and is updated frequently. It also provides a number of powerful tools which researchers can use to comprehensively annotate large gene sets from different biological angles. The DAVID Bioinformatics Resources is available for public access at website provided in "Relevant Websites section" (Huang *et al.*, 2007, 2008, 2009).

AmiGO

AmiGO ("see Relevant Websites section") is an open source web-based application developed and maintained by the GO Consortium to query, browse and visualize ontologies and related gene product annotation (association) data. It features a BLAST search, Term Enrichment and GO Slimmer tools and the GO Online SQL Environment. It displays the distribution of annotations

Table 1 List of widely used Bioinformatics tools in the enrichment analysis. Each tool has their distinct algorithm and features; the general procedure of the tools is take query gene list processed it using algorithm and statistics against their annotation database to generate resulting enriched gene set

HTSanalyzeR	2011	53	Hypergeometric test	Enrichment map and Network of enriched biological process

associated with a term and its children in both graphical and tabular formats via a bar chart viewer. It is a server-based Perl application that retrieves information from a database using go-perl and go-db-perl. It is publicly available at website provided in "Relevant Websites section" (Carbon *et al.*, 2009).

GOrilla

GOrilla is a web-based application developed using Java. It is publicly available at: "See Relevant Websites Section". It currently supports 8 organisms: *Homo sapiens*, *Mus musculus*, *Rattus norvegicus* and other model organisms such as *Saccharomyces cerevisiae*, *Caenorhabditis elegans*, *Drosophila melanogaster* and *Arabidopsis thaliana*. Functional analysis can be performed using this tool with either of two approaches. The first approach involves using a ranked list of genes enriched via the mHG statistics employed by GOrilla. The second approach involves the generally followed comparison of target and customized background dataset which is analyzed using a hypergeometric model employed by the tool. Thus, the input for GOrilla can be either a single ranked list of genes or two sets of genes (target and background). The output consists of color-coded trimmed Directed acyclic graph (DAG) of all annotated GO terms generated with the help of GraphViz tool. The color codes denote the level of significance of enriched GO term and the nodes are linked to the corresponding entry in a table. This table includes the enriched GO terms, p-values for enrichment and associated annotated genes. The results can be exported in excel format (Eden *et al.*, 2009).

FunRich

FunRich is a user-friendly, Windows-based, standalone application allowing users to perform enrichment analysis on their desktops. It is publicly available at: "See Relevant Websites Section" It allows users to perform functional enrichment analyses and interaction

network analyses on background databases without any restrictions on genomic, proteomic or metabolomics data. Users are given an option to select the database. It provides three database options: the FunRich database containing only human annotations, the UniProt database equipped with support for 20 different taxonomic levels and a Custom database that can be customized according to the user's requirements. This tool was developed in C# language using Microsoft .NET library. A hypergeometric distribution test is used to evaluate the statistical significance of enriched and depleted terms. False Discovery Rate (FDR) is implemented to correct for multiple testing by Bonferroni and Benjamini-Hochberg (BH) method. It provides a graphical representation of the data in the form of scalable Venn diagrams, column graphs, heatmap, bar graphs, pie chart and doughnut charts with customizable font, scale and color. Results can be saved in publication quality images and excel sheets (Pathan *et al.*, 2015).

GOplot

R is a commonly used platform by the community for data analysis and for the generation of high quality graphical representations of data. GOplot imports several R packages and is based on the graphical package, ggplot2, enabling users to generate a variety of multilayered graphs. This approach works with two types of input: Molecule lists with their expression levels, and results of functional enrichment analyses. It generates outputs offering different levels of detail: Bar plots or Bubble plots can be constructed to visualize the most enriched categories and Circle, Chord or Cluster plots can offer a more detailed representation of the analyzed results. The Circle plot has two layers: The inner layer is a bar plot representing the statistical significance of enriched terms, and the Outer layer displays the expression levels of particular molecules. The Chord plot has GO terms and molecules connected with ribbons wherever applicable. The Cluster plot displays a circular dendrogram clustered on the basis of their expression profile along with another layer of the associated GO terms. The R package GOplot is available via CRAN-The Comprehensive R Archive Network provided in "Relevant Websites section".

BiNGO

Biological Networks Gene Ontology tool (BiNGO) is a flexible, extendable, open-source Java tool to determine significantly overrepresented GO terms in a set of genes or a subgraph of a given biological network. It maps the functional annotations of gene sets on a GO hierarchy to produce a customizable visual representation in Cytoscape. It provides annotations for a wide range of organisms and these annotations are parsed from GO information available at NCBI. It provides two statistical tests for evaluating the significance of the associated GO terms: hypergeometric and binomial tests. Both of these tests generate p-values as a score for the statistical significance of the enrichment of the GO term. Multiple testing corrections are then applied to discard Type I errors. Multiple testing can be done by applying Bonferroni correction or FDR by BH correction. BiNGO results can be visualized in Cytoscape or can be saved in a tab-delimited text file. It is distributed under GNU General Public License and can be downloaded as a Cytoscape plugin (Maere *et al.*, 2005).

Blast2GO

Blast2GO ("see Relevant Websites section") is a biologist-oriented, high throughput, quality data-mining tool which can be used for functional annotation of a wide range of organisms. It is an operating system independent Java Application made available in Java Web Start (JWS).

GO annotation in Blast2GO proceeds through three basic steps: search for homologues by BLAST, GO term mapping and actual annotation. Blast2GO uses the Basic Local Alignment Search Tool (BLAST) to find sequences similar to your query set. A local BLAST or Web-based BLAST can be performed with parameters adjusted according to user's requirement. The BLAST results can be saved in a file in different formats.

Mapping is done to retrieve the GO annotations for high scoring BLAST hits. Resultant accessions retrieved after BLAST are then used to retrieve gene names, symbols and other IDs. These are then searched against the GO database.

Annotation is done to select the GO terms from the GO pool obtained by the mapping step and assigning them to the query sequences. GO annotation is carried out by applying an annotation rule (AR) to the found ontology terms. This rule seeks to find the most specific annotations with a particular selected level of reliability. For each candidate GO an annotation score (AS) is computed. The annotation rule provides a general framework for annotation but depends completely on how the different parameters at the AS are set. The functionality of InterPro annotations in Blast2GO allows retrieval domain/motif information in a sequence-wise manner. Corresponding GO terms are then transferred to the sequences and merged with already compiled GO terms. Blast2GO provides EC annotation through the direct mapping available at the GO website. Additionally, the KEGG map module allows for the display of enzymatic functions in the context of the metabolic pathways in which they participate. Visualization of the Blast2GO results can be constructed with the help of interactive directed acyclic graphs (DAG), pie charts and bar graphs which can be customized and filtered.

Most of its functionalities are available for free access at website provided in "Relevant Websites section" (Gotz *et al.*, 2008).

Case Study

Having seen the importance and application of functional enrichment analysis, the challenge now lies in the selection of the right tool for a particular analysis. There are plethora of tools that have been developed in the past to perform enrichment analyses, and

many more are emerging at a considerable rate. While most of the tools employ the same general approach, they differ in the way they represent the output and the interpretation of this enrichment dataset (Khatri and Draghici, 2005). Each of these tools has their own advantages and limitations. Thus, at the time of use, one should also have a clear understanding of the disparity between tools and choose the most appropriate tool that would best serve the user's research requirements. There are two excellent review articles (Khatri and Draghici, 2005; Huang *et al.*, 2009) on these tools, that should be consulted when selecting the analytical approach to employ for a particular dataset.

One of the most popular tools used worldwide is DAVID (Huang *et al.*, 2007, 2009), discussed above. For the convenience of the readers we present here a demonstration of the tool using publically available sample input data (i.e., the set of genes) derived from an earlier study (Gardina *et al.*, 2006), primarily to exemplify the use of the tool. DAVID can be accessed at the URL provided in "Relevant Websites section".

The study by Gardina *et al.*, identified 160 differentially expressed genes in 20 pairs of tumor and normal colon cancer samples. This case study uses this set of 160 differentially expressed genes to demonstrate functional enrichment analysis using DAVID (Huang *et al.*, 2007, 2009).

The 'Home' page of DAVID (Huang *et al.*, 2007, 2009) has two main options – 'Functional Annotation' and 'Gene Functional Classification'. The steps to follow are outlined below:

- (1) To begin, click on the 'Functional Annotation' option. A page opens up which will prompt the user to either paste a list of genes or upload a file containing the list of genes. The 'Select Identifier' asks the users to choose the appropriate type of gene ID that the input gene list uses. In the 'List Type', the user has to select whether the input gene list is a gene list or is to be used as the background gene set. Then click on 'Submit' (Fig. 1). The default database set as the background is the *Homo sapiens* genome database. However, the users may select different databases, according to the nature of their search and study. Choosing and setting up the right background for the analysis is a very crucial step. The general rule of thumb is to set a large background database such as the whole genome, as the results obtained will have more significant p-values as opposed to those resulting from concise background datasets (Huang *et al.*, 2009).
- (2) This analysis will produce an 'Annotation Summary Results' page that displays categories indicates that the genes have been annotated in Fig. 2. Users may choose to see additional results there.
- (3) Upon clicking the 'Functional Annotation Chart', the user can view a report that displays the annotation terms and the annotation database where the associated genes were mapped. It also displays the number and percentage of genes involved out of the total genes in the input list and the related terms list. The p-value of each result is displayed: the smaller the p-value the more enriched (Fig. 3a) a term is. Clicking on each annotation result will provide a list of genes from the input gene list that are associated with that particular annotation term (Fig. 3b).
- (4) The 'Functional Annotation Table' provides, for each input gene, the annotation terms, the database in which it is oriented, related genes and the species of interest (Fig. 4).
- (5) The annotation of the genes based on the Enrichment score is provided upon clicking the 'Functional Annotation Clustering' option. Here, the genes are clustered under an enrichment score, with a higher enrichment being the one with the higher

Key Concepts:

Terms/Genes Co-Occurrence Reliability
Finding functional categories based on co-occurrence with sets of genes in a gene list can rapidly aid in unraveling new biological processes associated with cellular functions and pathways. DAVID 6.8 allows investigators to sort gene categories from diverse annotation systems. Sorting can be based either the number of genes within each category or by the EASE score. [More](#)

Gene Similarity Search
Any given gene is associating with a set of annotation terms. If genes share similar set of those terms, they are most likely involved in similar biological mechanisms. The algorithm tries to group those related genes based on the agreement of sharing similar annotation terms by kappa statistics. [More](#)

Term Similarity Search
Typically, a biological process/term is done by a cooperation of a set of genes. If two or more biological processes are done by similar set of genes, the processes might be related in the biological network. This search function is to identify the related biological processes/terms by quantitatively measuring the degree of the agreement how terms share the similar participating genes. [More](#)

Integrated Solutions

Protein Annotation	Numerous public sources of protein and gene annotation have been parsed and integrated into DAVID 6.8. DAVID 6.8 contains information on over 1.5 million genes from more than 65,000 species. A list of protein or gene identifiers can be uploaded at all once to extract and summarize functional annotation associated with group of genes or with each individual gene. Data can be displayed in chart or table format or downloaded to the user's hard drive.

Fig. 1 Input page.

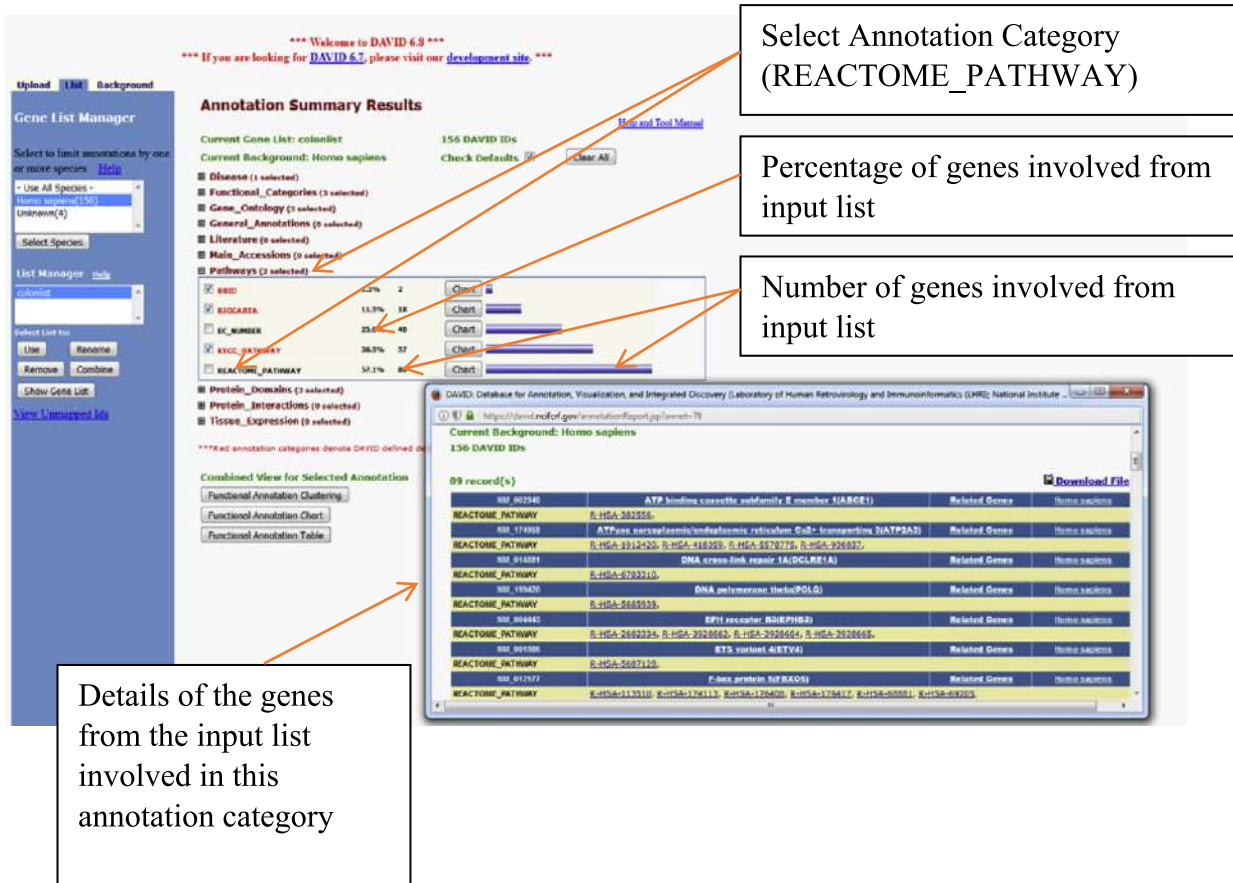

Fig. 2 The Annotation Summary page provides results on various functional annotation categories that the input genes have mapped with. Here, the 'Pathways' category shows the results of all the genes involved in the mentioned pathways, from the input gene list (i.e., 89 genes out of 156 genes).

value. The database associated as well as the number of genes involved, related terms and the p-values are also displayed. Clicking on each annotation result will provide a list of genes from the input gene list that fall under that particular cluster, with the particular enrichment score and p-value (Fig. 5).

- (6) Note: Although DAVID (Huang *et al.*, 2007, 2009) accepts a very large input gene list, the Functional Annotation Clustering option requires the users to input a maximum of 3000 genes only. Thus, users should split their input gene list into separate files, such that each file contains no more than 3000 genes.
- (7) Each result page provides an option to download the results in an easily documented manner.
- (8) In some cases, the user may not be aware of the gene ID type or may use a type that is not listed out in the Gene Identifier. DAVID has an in-built tool called the Gene ID Conversion Tool (Huang *et al.*, 2007, 2009), which enables the conversion of each gene entry into an acceptable Gene ID type.

Results

In the 'Functional Annotation Chart' (Figs. 3a,b), on selecting the first annotation result with the lowest p-value (i.e., $8.9E-8$), the list of the most enriched genes is displayed. In addition, from the 'Functional Annotation Clustering' result, on selecting the first result with enrichment score 3.12, a list of highly enriched genes is displayed. As an example, let us take the first gene which appears in this cluster, NM_014750. This represents DLG (Discs Large Homolog)-associated protein 5, which is a hepatoma up-regulated protein known to be a cell cycle regulator that plays a significant role in carcinogenesis. Similarly, users can gain invaluable volumes of information about genes and their functions through the various links provided by DAVID's results.

Future Directions

Users should test some of these and other tools in parallel or in an integrated mode in order to get relevant biological interpretations that best encapsulate their datasets. The databases described in this text are not comprehensive or exhaustive, and

should instead serve as a starting point for users to develop their own analytical workflows. Users should also keep in mind that GO annotations and databases are constantly being updated, so using different versions of the same resource may result in different outputs depending on temporal constraints. As new technologies continue to emerge and the cost of high-throughput experiments continues to fall, there will be a constant refinement of existing annotations to fit new advancements in scientific understanding. As such, using the most up-to-date resources is always recommended.

Closing Remarks

This article focuses on the various methods used for enrichment analysis and some of the popular tools and their properties **Table 2**. Using a test-case dataset, the steps involved in performing a functional enrichment analysis using the DAVID databases is depicted. A functional enrichment analysis is the initial step in any high-throughput experiment, allowing us to narrow down to specific set of genes/functions/pathways of relevance to the problem in hand. The information provided in this article could be considered as a fundamental resource which can be built upon to facilitate the functional enrichment analysis of any datasets.

Biographical Sketch

Srikanth Manda has completed his Masters in Biotechnology from Indian Institute of Technology, Bombay, thereafter, pursued a PhD in Bioinformatics from Institute of Bioinformatics, Bangalore and Johns Hopkins University, USA. During his Ph.D. work he has analyzed datasets from Whole Genome (WGS), Whole Exome (WES), Transcriptome, epigenome, miRNAome, proteome and phosphoproteome. His research interests involve multi-omics data analysis, integration and interpretation from high-throughput platforms using available tools and cloud based workflows.

Sudhir Jadhao is pursuing PhD in Genome Informatics at Queensland University of Technology. He specializes in NextGen sequencing and have analyzed data from diverse platforms (Illumina, PacBio, and Ion Torrent) and approaches (WGS, RNA-seq, miRNA, ChIP-seq, Microarray, Exome Sequencing, CNV). In his previous role as Research Assistant, Sudhir worked on understanding the role of non-coding RNA in regulation of the prostate cancer at the University of Macau.

Shivashankar H. Nagaraj is Advanced Queensland Research Fellow at Queensland University of Technology. The focus of his group is on the development and application of bioinformatics approaches that utilize large amounts of data to solve problems in Genomics and Proteomics. He has developed multiple Bioinformatics solutions (e.g., ESTExplorer, EST2Secretome, PGTools) that are valuable and of practical utility to the wider scientific community.

Prediction of Coding and Non-Coding RNA

Ranjeev Hari, Perdana University, Selangor, Malaysia

Introduction

Early biologists who primarily focused on prokaryotes noted that the majority (85%–90%) of genes were protein-coding and had them accounted for the major cellular processes. However, while complexity of organisms as driven by evolution became higher, the proportion of coding genes reduced gradually in relation to genome size (Mattick and Makunin, 2006). In one of the largest efforts to characterise human deoxyribonucleic acid (DNA), the Encyclopaedia of DNA Elements (ENCODE) project delineates that only about 2%–3% of the human genome are responsible for coding proteins. These genes which are transcribed appear minute in quantity when compared to the transcription of the non-coding regions which are at least 75% of the total genome (Djebali *et al.*, 2012).

The Central Dogma of Molecular Biology states that the genes from the genome (DNA) shall be transcribed into ribonucleic acid (RNA) molecules as per the quantum and mechanistic laws of physics and chemistry. Proteins are required to catalyse various cellular processes, and they are made when these RNAs called messenger RNAs (mRNA) are translated into amino acid sequence. The sudden discovery of non-coding RNAs (ncRNAs) in 1950s, however, were used to dispute the centrality of the Central Dogma. The infamous terms used for these non-coding DNA regions in the genome were “junk DNA” and is coupled with transcriptional “noise” for its RNA counterpart. By the 1970, there were key developments which suggested the role of ncRNAs in gene expression regulation of eukaryotes (Britten and Davidson, 1969; Kohne, 1970; Tomkins *et al.*, 1969). Till date, several possible functions are known for ncRNAs namely as epigenetic, transcriptional and post-transcriptional regulators often participating in DNA replication, splicing, translation, chromosome structure stability, and genome defence (Cheng *et al.*, 2005; ENCODE, 2007; Morris, 2012; Washietl *et al.*, 2007). Moreover, ncRNAs are also thought to have complex roles in cancer and other diseases. As a result, huge efforts are ongoing in trying to understand better the various classes of ncRNAs of its roles and functions in living systems.

RNA Universe

RNA is one of the three essential biopolymers apart from DNA and protein for biological life and are intermediaries to DNA and protein function as per the central dogma. It is an important catalyst for various biological processes and in some instances, once phosphorylated it can even become a subunit of ATP, NADH, and other metabolic compounds. Being commonly found in single-stranded form, it is flexible to take on a 3-dimensional structure better than the double-stranded DNA. Consequently, its structure has protein-like hierarchy that are defined into secondary and tertiary level of structure. Some of the diverse types of secondary structural elements are hairpin loops, 180° bend backbone, internal loops where sequences cannot form base pairs, multibranch loops where two or more regions form a close structure, and other bulge loops. These secondary structural elements can display distinct functions in a cell and are usually structurally conserved (Mathews *et al.*, 2004).

With diverse functions, and as new RNA are being discovered and studied there are different types of RNA classification systems that emerged. Most commonly, RNAs are classified by function and size. Functionally; as examples, RNAs; such as, messenger RNA (mRNA); better known as coding gene or coding RNA are involved in protein synthesis, ribosomal RNA (rRNA) that produce ribosome and aid mRNA by interacting with tRNA during translation, transfer RNA (tRNA) that are in triplet base carrying amino acid precursors for protein anabolism, RNA that involved in post-transcriptional activity are small nuclear RNA (snRNA) that are important in introns removal of heterogenous nuclear RNA (hnRNA), small nucleolar RNA (snoRNA) are essential in RNA mutation, ribonuclease P (RNase P) acts as a ribozyme that cleaves precursor sequences of tRNA, telomerase RNA (TER) are involved in eukaryotic RNA function of extending telomeres and small-interfering RNA (siRNA) are gene silencers and regulators. RNAs are also divided based on size into three groups; which is small ncRNAs, medium ncRNAs, and long ncRNAs (Akman and Erson Bensen, 2014; Brosius and Raabe, 2016; Gomes *et al.*, 2013a; Ma *et al.*, 2013; Santosh *et al.* 2015). An instance of the organisation of the RNA landscape by size is described in Fig. 1.

Coding RNA

Central Dogma proposed by Francis Crick explained the conversion flow from DNA which carries genetic information to protein which is a functional product (Crick, 1970). It is also a 2-key steps gene expression process, where transcription produces mRNA by RNA polymerase and translation convert information from mRNA into protein sequence. While RNA mediates majority of the transfer of information based on the proposed model by Crick (Table 1), wherever RNA is being expressed with no translation to protein, it is then largely labelled simply as RNA or non-coding RNA (ncRNA).

In coding genes, DNA will be transcribed into pre-mRNA; an immature single strand of mRNA, which will be processed into mature mRNA transcripts that are functional. In eukaryotes, 3'-end cleavage of transcripts generated by RNA polymerase II (pol II)

Fig. 1 RNA universe classification based on coding and non-coding RNA.

Table 1 Nine possible transfers in three classes as per Crick's central dogma

Class	Possible transfer
General transfer	DNA replication
	Transcription
	Translation
Special transfer	RNA replication
	Reverse transcriptase
	Protein synthesis without mRNA template
Unknown transfer	

Source: Reproduced from Crick, F., 1970. Central dogma of molecular biology. Nature 227, 561–563.

is a universal step of gene expression that proceeds through the recognition of cis-acting elements of the pre-messenger RNA (mRNA). It will then undergo 5'-capping, followed by intron removal and methylation, as well as 3'-cleavage and polyadenylation (Fig. 2; Millevoi and Vagner, 2009). A mature mRNA, depending on the host organism, can be translated to protein based on a triplet sequence called codon for each amino acid by a specific codon to amino acid translation table.

Gene prediction programs makes use of the molecular and structural signatures of genes as important features in software algorithms predicting protein coding mRNA transcripts. Other approaches based on sequence similarity (homology) search by using BLAST searches are commonly used especially when high quality data is available in a sequence database of genes, EST or protein. However, since only half of genes being discovered have significant homology to databases, *ab initio* gene prediction methods are used instead. Gene prediction programs that are using algorithms such as dynamic programming, Hidden Markov Models (HMM), and neural networks includes GeneID, GENSCAN, FGENSESH, and Grail (Blanco *et al.*, 2007; Burge and Karlin, 1997; Salamov and Solovyev, 1998; Xu *et al.*, 1996).

Non-Coding RNA

Essentially, RNA or ncRNA is a functional RNA molecule that are functional without having to translate into protein. Common functional RNA that are involved in cellular housekeeping includes the transfer RNA (tRNA) and ribosomal (rRNA) which are known to be involved with mRNA during translation. The many classes of ncRNAs have diverse yet essential roles in biological processes, including ribonucleoprotein (RNP) in translation, snoRNA in alternative RNA splicing regulation, Y RNAs in DNA replication, enhancer RNAs (eRNAs) which promote gene expression in gene regulation and other epigenetic ncRNAs such as miRNA, siRNA, piRNA and lncRNA involved in modifications to various DNA processes (Collins *et al.*, 2011; Storz, 2002). However, of the many ncRNAs being newly identified, most have no known function and are simply identified as junk RNA (Palazzo and Lee, 2015). Nevertheless, large bodies of evidence are being accrued that implicate ncRNA such as miRNAs and snoRNAs in diseases; such as, Autism, Alzheimer's and even some type of cancers (Ding *et al.*, 2008; Nakatani *et al.*, 2009; Shen *et al.*, 2009) (Fig. 3).

In previous studies, efforts in identifying ncRNAs often centred in experiments involving complementary DNA (cDNA) cloning and genomic tiling arrays (Lund *et al.*, 2014; Yazaki *et al.*, 2007). Some experimental strategies utilize *in vitro* translation to distinguish between ncRNAs and mRNAs where positive translation indicate that a transcript is an mRNA (Borsani *et al.*, 1991;

Fig. 2 The transcription process of information from DNA to RNA.

Fig. 3 Biogenesis of miRNAs, siRNAs, piRNAs and lncRNAs.

Galindo *et al.* 2007; Tupy *et al.* 2005). These experiments are often time-consuming and costly, requiring enough RNA samples while being limited to identifying long ncRNAs (lncRNAs). Researchers are increasingly using computational methods to offset these limitations by incorporating them in their experimental methods especially with the reduction in cost of high-throughput technologies such as next generation sequencing (NGS).

Coding and Non-Coding Prediction Approaches

Differentiating non-coding and coding regions in a genome can be approached computationally, moreover, it may be viewed as a classic type of statistical categorisation problem. Computationally, identifying and cataloguing vast information from genomic and transcriptomic data can be mainly divided into *ab initio* and evidence-based prediction methods while some are based on a hybrid of both methods. Generally, in *ab initio* prediction, the algorithm distinguishes from coding and non-coding genes relatively quickly from the genomic and transcript sequences provided as input. The prediction is derived upon known features of the coding gene such as the start and stop codons, open reading frame, splice and polyadenylation sites. Such *a priori* information will be applied as features in machine learning algorithms for better prediction accuracy. In contrast, evidence-based prediction method would use known information from DNA/RNA and protein sequences to generate predictions by mapping and comparison. In order to curtail the high false positive rates in *ab initio* prediction methods, supported by dwindling costs of NGS, evidence-based prediction is made practical for application in larger datasets. Furthermore, the application of both *ab initio* and evidence-based prediction into a hybrid approach is a natural progression in the field of gene prediction where, for instance, the use of gene expression evidence and subsequent genome mapping in generating better *ab initio* gene models is having widespread attention. Given transcript RNA sequences, many prediction software can predict its class of coding potential with relatively high-accuracy.

Several tools are available to discriminate mRNA and RNA which work on diverse set of features which are often shared in its approaches (Fan and Zhang, 2015). Often some software tools; such as, CNCTDiscriminator which utilizes machine learning as an ensemble of several statistical features of base composition, open-reading frame (ORF), and secondary structures in generating its predictions (Biswas *et al.*, 2013). Other example of software widely used in distinguishing coding and non-coding transcripts are COME (Hu *et al.*, 2017), CPC (Kang *et al.*, 2017; Kong *et al.*, 2007), CNCI (Sun *et al.*, 2013), CPAT (Wang *et al.*, 2013b), PhyloCSF (Lin *et al.*, 2011), PLEK (Li *et al.*, 2014), FEELnc (Wucher *et al.*, 2017), Lncrna-ID (Achawanantakun *et al.*, 2015) and PORTRAIT (Arrial *et al.*, 2009). These tools attempt to achieve similar goals of classifying mRNA and RNA, however, the focus for some are in specific organisms and RNA classes while others are general purpose classifiers.

Besides differentiating coding and non-coding RNAs, these computational methods could also be used in identifying and cataloguing functional RNAs by its class (Fig. 4). Evidence-based methods utilize homology information of the nucleotide sequences and sometimes its structural properties as well. Homology-based software tools using sequence homology includes Basic Local Alignment Search Tool (BLAST) (Johnson *et al.*, 2008), SSearch (Goujon *et al.*, 2010), BLAST-like alignment tool (BLAT) (Kent, 2002); while structural homology tools that usually have better prediction accuracy include INFERNAL (Nawrocki *et al.*, 2009) and RSearch (Klein and Eddy, 2003). Apart from homology-based software, ncRNA can be identified using *ab initio* algorithms such as CRITICA (Badger and Olsen, 1999) and ESTscan (Iseli *et al.*, 1999) based on sequence features; MiPred (Jiang *et al.*, 2007), Mfold (Zuker, 2003) and RNAfold (Hofacker, 2003) based on structure while miRDeep (Friedländer *et al.*, 2011) and snoSeeker (Yang *et al.*, 2006) based on sequence features from deep sequencing data (Wang *et al.*, 2013a). Moreover, hybrid integration of both homology and *ab initio* algorithms in RNA prediction is also applied in some software such as MASTR (Lindgreen *et al.*, 2007), pTRNAPred (Gupta *et al.*, 2014), and Infernal (Nawrocki *et al.*, 2009).

Fig. 4 Software tools for ncRNA prediction is divided into three methods: homology-based, *ab initio*, and hybrid method.

Small RNA

Sequences of RNAs within 50 nucleotides are classified as small non-coding RNA and are known to primarily control stability of mRNA translation by repressing or activating binding of ribosome to mRNAs (Storz *et al.*, 2004). Example of small ncRNAs that are commonly found in eukaryotes are microRNA (miRNA), piwi-interacting RNA (piRNA), short-interfering RNA (siRNA), tRNA-derived stress-induced RNA (tiRNA), and centromere repeat-associated small RNA (crasiRNA). The three major types of small ncRNAs play important role in gene silencing pathways especially in eukaryotes and protecting cell/genome against viruses, mobile repetitive DNA sequences, retro-elements and transposons are miRNAs, siRNAs and piRNAs (Gomes *et al.*, 2013b; Moazed, 2009).

One of the general purpose bioinformatics software that can be used to predict small ncRNA is RNAz (Gruber *et al.*, 2010; Washietl *et al.*, 2005). RNAz uses a combined approach of support vector machines (SVM) regression with binary classification technique and applies minimum free energy (MFE) structural prediction algorithms. Two other important features used by RNAz in this approach are RNA's intrinsic unusual thermodynamic stability (by comparing MFE of native sequence to large number of random identical in length and base composition sequences) and structural conservation (by using RNAalifold) (Gruber *et al.*, 2010; Washietl *et al.* 2007, 2005). Fig. 5 is given to better illustrate an example of sRNA prediction workflow using RNAz.

Microna (Mirna)

As one of the most studied class of ncRNA, microRNA (miRNA) are small, endogenous, single-stranded RNAs approximately 22 nucleotides/bases in size. They are found in both animals and plants and are evolutionary conserved units (Baulcombe, 2004; Zhang *et al.*, 2007). As small regulatory molecules, they are expressed independently, possess their own promoters and can be regulated by a distinctive set of transcription factors (Gulyaeva and Kushlinskiy, 2016). The target of miRNA commonly is messenger RNA (mRNA).

MicroRNAs functionally govern cell proliferation (Hwang and Mendell, 2006), differentiation and apoptosis (Xia *et al.*, 2017). They are sometimes related in regulation and reprogramming of cellular metabolism in cancer. In some instances, deregulated miRNAs have been correlated with cancers. For example several types of miRNAs that have been proved to be up regulated in cancerous tissues such as let-7e, miR-151p, miR-222, miR-21, miR-155, and miR-221 (Sarkar *et al.*, 2010). This RNA class is well known in affecting transcription levels in animals exerted by major silencing mechanism from destabilization through a cleavage-independent process (MacFarlane and Murphy, 2010). Moreover, miRNAs are noted in diverse functions in cellular life including cell cycle, development, signal transduction, metabolism, metastasis, cell proliferation, differentiation and apoptosis (Mahmoudi and Cairns, 2016).

Computationally, several prediction algorithms have been developed in identifying miRNAs. For instance, miRscan compares the identified putative structures with known miRNA features like 3' and 5'-stem conservation while another tool, miRseeker, attempts to select hairpins sharing similar nucleotide divergence patterns to a reference set (Lai *et al.*, 2003; Lim *et al.* 2003; Terai *et al.*, 2007). These two main tools identify sequences that can form hairpin structures based on RNAfold and Mfold based on the conserved intragenic sequences. Besides that, there are several tools that have been developed to predict miRNAs for a variety of species, for example, the HMM-based tool ProMir, and improved ProMir II (Nam *et al.*, 2006, 2005), MiRRim is another HMM-based to achieve high-performance identification of new human miRNAs (Terai *et al.*, 2007), while HHMMiR predicts de novo miRNA hairpins in the absence of evolutionary conservation (Kadri *et al.*, 2009).

Piwi-Interacting RNA (Pirna)

Piwi-interacting RNAs (piRNAs) are a distinct class of miRNAs which are mainly expressed in germline cells with approximately 24–32 nucleotides in length (Aravin *et al.*, 2006). Setting it apart from miRNAs, it has a bias for 5'-uridine common to piRNAs in vertebrates and invertebrates and known to possess lesser secondary structure conservation. They are generally detected with Piwi proteins as they get processed into piRNAs from longer precursor transcripts (Aravin *et al.*, 2006; Lau *et al.*, 2006). Piwi-interacting RNAs are important in genetic and epigenetic regulatory factors for germ cell maintenance, genome integrity, mRNA stability, DNA

Fig. 6 General structure of siRNA.

methylation and retrotransposon control (Zuo *et al.*, 2016). It has some role in gene silencing and are involved in cancer pathways such as piRNAs piR-651 found to be overexpressed in many of cancer cell lines, piR-823 seen in many types of cancer development, and piR-Hep1 is up regulated in hepatic cell carcinoma (Cordeiro *et al.*, 2016; Ng *et al.*, 2016). Having such significance, computational methods offer quick identification of putative piRNA sequences.

Generally, a few of the computational prediction tools for piRNAs include Luo's method, Betel's method, piRNApredictor and Piano. Each attempt to differentiate transposon-derived piRNAs from non-piRNAs from different sequence and physiochemical features such as spectrum profile, mismatch profile, subsequence profile, position-specific scoring matrix, pseudo dinucleotide composition, and local structure-sequence triplet elements (Betel *et al.*, 2007; Luo *et al.*, 2016; Wang *et al.*, 2014; Zhang *et al.*, 2011). Recently, IpiRID webserver tool improved on several of the previous software tools prediction accuracy on human, mouse and fly datasets (Boucheham *et al.*, 2017).

Short Interfering RNA (Sirna)

Short interfering RNAs are generated from dsRNAs (double strand RNAs) and consist of two RNA strands which is antisense and a sense strand that form a duplex 19–25 bp in length with 3' dinucleotide overhangs as shown in Fig. 6. The antisense strand is a perfect reverse complement of the intended target mRNA.

Some of the functions and roles of siRNAs are mainly in post-transcriptional gene silencing (PTGS) or translational inhibition, protection from exogenous DNA, participation in epigenetic mechanisms and to maintain genome integrity via transcriptional silencing. Due to its ability to knockout genes, it has been exploited for commercial applications to rapidly study gene function *in vivo*. Thus, much of the computational applications of siRNA is in the design of optimal targeting of siRNA sequences to knockout genes. Thereafter, prediction of siRNAs can be used to develop screening protocols that can be used to find novel pathway, validating targets of cellular processes associated to diseases such as cancer, HIV infection, or hepatitis.

Computational prediction for siRNA is Sylamer, method to find significantly over or under-represented words in sequences according to a sorted gene list. Usually used to find significant enrichment or depletion of microRNA or siRNA seed sequences from microarray expression data.

Medium Non-Coding RNA

Mid-size RNA class have lengths that range from 60 to 200 nt which include transfer RNA (tRNA), small nucleolar RNA (snoRNA), small nuclear RNA (snRNA) and small cytoplasmic RNA (scRNA) (Bhan and Mandal, 2014).

Transfer RNA (tRNA)

The transfer RNA (tRNA) is a common RNA molecule 76–90 nt in length and serves as an adaptor molecule between mRNA and protein. During translation, tRNA acts as a carrier of amino acids to growing polypeptide chain. Besides that, tRNA is also known to be involved in non-protein synthetic processes in retrovirus life cycle. (Sharp *et al.*, 1985).

The tRNA has a cloverleaf structure which consists of four helices and three hairpin loops. The four helices are the acceptor (AA) helix (or stem) carrying charged amino acid by the cognate aminoacyl synthetase, the dihydrouridine (D) hairpin containing the modified base dihydrouracil; the anticodon (AC) hairpin having the apical loop that presents the anticodon triplets; and the thymine (T) hairpin containing the thymine base unusual in RNAs (Westhof and Auffinger, 2001). By having such highly conserved structural characteristics, established computational tools to predict tRNA from sequences are available such as tRNAscan SE and ARAGORN (Laslett and Canback, 2004; Lowe and Eddy, 1997).

As tRNA perform essential biological functions, mutation of tRNA may cause serious human disease, including pathological stress injuries, cancer and neurodegenerative disease. A special bioinformatics tool for tRNA sequence modification investigation is tRNAmopred. The tool allows the prediction of post-transcriptional modifications of tRNAs in regards to position and modification type (Machnicka *et al.*, 2016).

Small Nucleolar RNA (Snorna)

Small Nucleolar RNA (snoRNA) is one of the medium-sized RNA which is approximately 60 to 170 nt in size and prominent in both Archae and Eukaryotes, however, absent in bacteria (Jorjani *et al.*, 2016; Bhattacharya *et al.*, 2016). The locus of snoRNA biosynthesis in yeast originates from a monocistron while for plants in a polycistron. Mainly, snoRNAs play an important role in guiding other

RNA's chemical modification particularly in rRNAs and snRNAs, which are divided into three motif-based classes of antisense C/D box with 2'-O-methylation of ribonucleotides, antisense H/ACA box with pseudouridylation and small Cajal body-specific RNAs (Bhattacharya *et al.*, 2016). Loss of copy of snoRNAs leads to some debilitating human diseases such as Prader-Willi (PWS) and Angelman (AS) syndrome. Implicating complex neurogenetic disorders, PWS is characterized by intellectual impairment, obesity and type 2 diabetes, and short stature while AS symptoms show mental retardation or small head and specific appearance (Ding *et al.*, 2008; Skryabin *et al.*, 2007). In PWS, the cause is attributed to gene imprinting epigenetics on chromosome 15q11.2 and micro-deletion of the paternally inherited 29 copies of SNORD116. On the other hand, AS is attributed to the loss of maternal region chromosome 15 of Ube3A gene. Conversely, duplication of MBII52 snoRNA closely related to common neuropsychiatric disorder with impaired communication disorder, autism by affecting the serotonin 2c receptor (Nakatani *et al.*, 2009).

A number of bioinformatics tool are available for snoRNA detection such as snoScan for C/D box methylation-guide snoRNAs and snoGPS servers for H/ACA pseudouridylation-guide snoRNAs. (Schattner *et al.*, 2005). Besides that, snoSeeker includes two programs (CDseeker and ACAseeker) for screening alignments of whole genome putative snoRNA candidates in order to identify snoRNAs (Yang *et al.*, 2006). Apart from this, snoReport, which is one of the bioinformatics snoRNAs approach with unknown targets, allow to recognize two major classes snoRNAs with combination of RNA secondary structure prediction and snoRNABase collection (Hertel *et al.*, 2007).

Small Nuclear RNA (Snrna)

Small nuclear RNA (snRNA) is one of the small RNA with an average size of 150 nt. Eukaryotic genomes code for a variety of non-coding RNAs and snRNA is a class of highly abundant RNA, localized in the nucleus with important functions in intron splicing and other RNA processing (Maniatis and Reed, 1987). Generally, in transcript splicing, snRNA presents as a ribonucleoprotein particles (snRNPs) along with additional proteins that form a large particulate complex (spliceosome) bound to the unspliced primary RNA transcripts in order to mediate the process. Besides splicing, additional evidence indicate snRNPs function in nuclear maturation of primary transcripts in mRNAs, gene expression regulation, splice donor in non-canonical systems and in 3'-end processing of replication-dependent histone mRNAs (Buratti and Baralle, 2010; Ideue *et al.*, 2012; Lasda and Blumenthal, 2011).

Long Non-Coding RNA

Transcribed RNAs with more than 200 nt long are generally classified as long non-coding RNA (lncRNA). This class of RNA is large and diverse and could be further classified by position of transcription (Intergenic, Intronic, Antisense, Sense and Overlapping ncRNAs) (Fig. 7), structure of RNA (Linear, Circular) and functionality (Bhan and Mandal, 2014; Peschansky and Wahlestedt, 2014). When functionally classified, there are four subcategories divided by mode of action; such as, lncRNAs, which act as either signals, decoys, guides, or scaffolds (Nie *et al.*, 2015).

Alteration in lncRNAs is closely related to human neurological disease, cancer as well as aging. Over expressed of lncRNAs which located on chromosome 2q32 causes prostate cancer apart from abnormal of lncRNAs splicing event allow tumour-suppressor lncRNAs, metastasis associated lung adenocarcinoma transcript 1 (MALAT1) widely involved of lung cancer, pancreatic cancer and cervical cancer. Besides, MEG3, HOTAIR, and lincRNA-p21 act as oncogenic ncRNAs to allow them associated with disease susceptibility. For instance, loss and imprinted MEG3 may contribute to tumour progression; such as meningiomas, colorectal carcinoma, and type 1 diabetes, respectively. (Bhan and Mandal, 2014; Chen *et al.*, 2016). Autosomal dominant facioscapulohumeral muscular dystrophy (FSHD) is caused by deletion of chromosome 4q35; yet, Duchenne muscular dystrophy occur commonly and severely due to deregulation of lncRNAs expression. (Neguembor *et al.*, 2014). In addition, elevated antisense lncRNA transcript of beta secretase 1 (BACE1) is correlated to Alzheimer's disease (Faghihi *et al.*, 2008).

As outlined previously, the identification and study of lncRNAs is of major relevance to human biology and disease since they represent an extensive, largely unexplored, and functional component of the genome (Mattick and Makunin, 2006; Ponting *et al.*, 2009). For instance, although some lncRNAs have been shown to affect in human diseases, these studies are limited by the lack of lncRNA annotations. Therefore, the identification of high-quality catalogues of lncRNAs and its expression in tissues is important work. On the contrary, similar information for protein-coding genes has long been obtainable.

In order to facilitate the growing interest in ncRNA and particularly lncRNA, generating high-confidence catalogues of lncRNA for further study is crucial. Genome sequencing efforts in association with RNA-seq in several studies were able to catalogue lncRNA of various genomes of the sponge, mouse, bovine, and human. These studies have shown that a large portion of these genomes are actually transcribed and could aid the discovery of many more non-coding transcripts (Carninci *et al.*, 2005; Harrow *et al.*, 2006). Furthermore, some studies have focused on large intergenic non-coding RNAs (lincRNAs) (Ponjavic *et al.*, 2007; Guttman *et al.*, 2009; Khalil *et al.*, 2009; Orom *et al.*, 2010), the non-coding transcripts which are away from protein-coding regions.

Recent advances in whole-transcriptome RNA sequencing (RNA-seq) and computational methods for transcriptome reconstruction now provide an opportunity to expansively annotate and characterize lncRNA transcripts (Garber *et al.*, 2011; Guttman *et al.*, 2010; Trapnell *et al.*, 2010). Certainly, an initial application of this method in three mouse cell types characterized the gene structure of more than a thousand mouse lincRNAs, most of which were not identified before (Guttman *et al.*, 2010). With logical frameworks that have

Fig. 7 Classification of lncRNA by transcript expression position in relation to gene and strand origin.

been thoroughly established in previous studies, it is now possible to catalogue and curate high-confidence lncRNA (Pauli *et al.*, 2012). Generally, a well-designed filtering pipeline can be used to arrive at putative lncRNA that can be further assessed for protein-coding capacity. The final set that exhibit poor protein-coding potential will remain as high-confidence lncRNA.

Many studies employ their own pipeline and criteria for filtering their transcript dataset from RNAseq. However, lately there has been software programs that execute the workflow systematically to catalogue the lncRNA; such as, lncrna-screen, FEELnc, and Annocript (Gong *et al.*, 2017; Peng *et al.* 2017; Wucher *et al.*, 2017). Generally, the lncRNA identification pipeline will require the assembly of reads into transcripts models which will then be merged, low-confidence transcripts removed, both potential and actual protein-coding transcripts removed, and having the final set of lncRNA transcripts classified (Ulitsky, 2016).

Besides computational identification, since lncRNAs are known to contribute widely in human diseases, computational methods to predict association with diseases are also available. LDAP (lncRNA-disease association prediction) is proposed to predict interaction between lncRNA with susceptibility disease and uses Smith-Waterman algorithm to calculate sequence similarity and several methods to calculate disease similarity (Lan *et al.*, 2016). Apart from LDAP, LRLSLDA (Laplacian Regularized Least Squares for lncRNA-Disease Association) that associates functionally similar disease with lncRNA as well as LNCSIM (LRLSLDA-lncRNA Functional Similarity Calculation Model) that calculate semantic similarity between associated disease are powerful computational approach which could help find probable relationship of lncRNA to diseases (Chen *et al.*, 2015).

Introduction

Vaccination is one of the most efficacious medical interventions that have decreased human morbidity and mortality in all regions of the world. It not only has dramatically reduced the incidence of numerous diseases (Hilleman, 1985; Andre *et al.*, 2008), such as measles, diphtheria, mumps, rubella, tetanus, yellow fever, pertussis, and poliomyelitis, but also eradicated the dreaded smallpox viral infection (Strassburg, 1980). Efforts are currently also focused on developing vaccines for treatment of other diseases (Ada, 2003). This triumph over infectious diseases has been achieved by using either killed or attenuated conventional vaccines. A conventional or prophylactic vaccination is based on deliberate exposure to non-virulent form of the pathogen to establish immunity from subsequent exposure to the virulent form of the pathogen (Lee *et al.*, 2012). This approach requires little knowledge of the molecular nature of the individual pathogen antigens or the immune responses they elicit. To date, this approach has undoubtedly been the most successful.

There is, however, an ongoing trend towards emerging infectious diseases (Fauci, 2001; Fauci *et al.*, 2005) against humankind in different parts of the world. These diseases are caused by the emergence of new pathogens, resurgence of old ones, constantly mutating pathogens, drug-resistant pathogens, and even include pathogens used as agents of bioterrorism. Previously undescribed pathogens, such as severe acute respiratory syndrome (SARS), bird flu (avian influenza), mad cow, and HIV/AIDS, are appearing at an increasing frequency. On the other hand, old diseases such as ebola, hanta, dengue and cholera, among others, are invading populations from which they have disappeared or cross species barrier to invade new species. Occasionally, pathogens mutate (or recombine) and then they adapt and show up as new variants that evade the host's acquired immunity. The annual influenza epidemics are generally due to genetically drifting strains of influenza that differ slightly from previous strains (Bouvier and Palese, 2008). The development of drug-resistance pathogens, such as malaria, pneumococci, enterococci, and tuberculosis, has increased over the years, partly due to the widespread and inappropriate use of drugs (Knobler *et al.*, 2003). Moreover, the pathogens responsible for the emerging infectious diseases are also of potential use as bioterrorist weapon (Ryan, 2008). For these reasons, emerging infectious diseases continue to pose threats to public health (Morens and Fauci, 2013). Therefore, there is a need for more effective vaccines to help reduce human morbidity and mortality from emerging infectious diseases.

The last decade has seen significant advances in new technologies for the development of new vaccines. These technologies, combined with our understanding of host response to foreign antigens, have laid the foundation for rapid advances in vaccinology. Few potential candidate approaches for this new family of vaccines (Arnon and Ben-yedidia, 2003; Minichiello, 2002; Babiuk, 1999; Nandy and Basak, 2016) are subunit vaccines, genetically engineered live vaccines, and polynucleotide (DNA or genetic) vaccines. All these new directions in vaccine development have something in common; their most important challenge is the discovery of key antigens from the array of proteins encoded by the pathogen genome that are able to elicit protective immune response against these pathogens and are effective for majority of the human population. The presence of genetic variation in the genes of the host immune system across the human population and the genomes of the pathogen variants make this a multi-dimensional and a combinatorial problem.

Since 1980s, the focus of vaccine design has been on the pathogen's variable domains, mutants, multivalent coverage and not so much on conserved regions (Plotkin, 2005). However, a large body of data is building up in the field of vaccine design and epitope prediction that points to the neglected aspect of conserved epitopes as important targets of vaccine development. In fact, evidence is accumulating that while many variable regions are highly antigenic, sufficiently large number of them are actually non-immunoprotective and have been exploited by viruses and other pathogens for immune escape and may lead to immunopathology (Haydon and Woolhouse, 1998). Conserved epitopes were thought to be unimportant due to their lack of immunogenicity (Bona *et al.*, 1998; Li *et al.*, 2011). However, the immunogenicity of such conserved epitopes especially those which are immune-protective and conserved amongst many variants and mutant strains, can be boosted using adjuvants, which are chemicals or approved drug molecules. Moreover, conserved epitopes also help address the issues of ethnicity ("pan-haplotype responsive") compared to variable epitopes (Khan *et al.*, 2008). In addition, the conserved epitopes can circumvent vaccine design issues of escape mutants and the need of using the latest strains. In particular, if a set of conserved, immunogenic, and immunoprotective epitopes are suitably boosted, they will not elicit mutations in the pathogen, and thus can be reasonably predicted to remain unchanged in the next season of infection. The possibility of extended efficacy of vaccines would be a tremendous advance for the vaccine industry and will potentially serve the global population with protection against infections (Sylvester-Hvid *et al.*, 2002; De Groot *et al.*, 2004; Sette *et al.*, 2001; Raman *et al.*, 2014; Khan *et al.*, 2017).

Vaccine informatics, a fledgling sub-field of reverse vaccinology, has the potential to develop effective vaccines (Hegde *et al.*, 2017; Khan *et al.*, 2017). With the rapid expansion of vaccine related data (host and pathogen) stemming from both classical and high-throughput genomic/proteomic approaches, identifying conserved, robust, immunogenic, and immunoprotective epitopes manually from this large data pool is inefficient. Vaccine informatics is a practical science for designing new vaccines with a focus

on bioinformatics-driven acquisition, manipulation and analysis of data related to the immune system and disease agents (Raman *et al.*, 2014). It provides a means for systematic study of big data, pre-screening of targets, and facilitates experimental design for validation by a small number of key experiments. The bioinformatics support can be divided into two, the standard bioinformatics support and the more specialised immunoinformatics support (Petrovsky *et al.*, 2003). The standard support includes basic bioinformatics functions, such as sequence comparison and alignment, database searching, hunting for patterns and profiles, 3D-structure analysis and modeling, and data annotation (reviewed in Brusic and Petrovsky (2003)). Immunoinformatics is a more targeted bioinformatics support with an emphasis on data-warehousing and mining of immunological data, such as prediction of immunogenicity (Soria-Guerra *et al.*, 2015; Brusic and Petrovsky, 2003). Vaccine researchers are taking advantage of these bioinformatics approaches, in combination with experimental validation, to discover and facilitate better understanding of the components of the human immunome, which then aid in the design of new vaccines. The immunome can be defined as the complete set of genes and proteins of the immune system. Highly accurate target predictions can diminish discovery cost by 10–20 folds (De Groot *et al.*, 2002; Kast *et al.*, 1994).

Background

In the human and higher vertebrate host, the major functions of the immune system are the maintenance of homeostasis, surveillance and tolerance to self-structures, and defence followed by immunity against pathogens (Yatim and Lakkis, 2015). The immune system is widely distributed in the body and comprises of immune organs, tissues, and cells, connected as a complex, but tightly regulated network (Jerne, 1993; NIH, 2003; Nicholson, 2016). In general, the processes that take place at the molecular level and cellular level largely initiate and regulate the function of the immune system. A healthy immune system will discriminate 'non-self' or foreign antigenic proteins from those that are normally present ('self') in an organism and will raise appropriate responses. The number of self-structures is large, but finite; the number of non-self structures is practically infinite. In the cell, both self and non-self proteins are digested by the proteasomes into short peptide fragments, which are then bound by major histocompatibility complex (MHC) molecules to form peptide/MHC complexes and are displayed on the surface of host cells (Vigneron and Van den Eynde, 2014). These peptides are recognition labels, which display the contents of host cells to T cells of the immune system. The presence of non-self peptides is a prerequisite for the initiation of immune responses. Peptides produced by degradation of intracellular proteins bind MHC class I molecules and are recognised by CD8⁺ T cell receptor (Shastri *et al.*, 2002; Chowell *et al.*, 2015; Blum *et al.*, 2013). MHC class II molecules present peptides, produced by degradation of proteins of extracellular origin, on the surface of antigen-presenting cells to CD4⁺ T cells (reviewed in Lennon-Duménil *et al.* (2002)). A major function of CD8⁺ T cells is to recognize and destroy cells infected by pathogens (Nicholson, 2016). Peptides displayed by the MHC class II molecules mainly serve to regulate immune responses; they are crucial for the initiation, enhancement and suppression of immune responses.

Driven by methods of molecular and cell biology, significant advances in the understanding of immunological processes have been made during the last two decades. This progress over the years resulted in the continuous accumulation of huge amount of immunological data obtained experimentally. This growing number of immunological data and the high complexity of the functional and structural foundation of the immune processes created a need for improved data management to enable advance data analysis. The need to manage and analyse this growing amount of complex data has led to the development of a number of immunological databases (Brusic *et al.*, 2000), such as SYFPEITHI and MCHPEP, IMGT and FIMM, and complex computational models (Petrovsky and Brusic, 2002). The purpose of immunological databases is to facilitate the collection of, access to, and use of immunologically relevant data. One of the applications of the databases in immunology is for vaccine research and development by using complex computational models in combination with experimental approaches to help precise our understanding of antigen presentation and recognition by the immune system.

The combined effort between experimental and computational immunology provided us with a new perspective to designing vaccines that will be effective across demographic boundaries. Previously, the extreme degree of polymorphism observed in the MHC posed limitations for the development of such a vaccine because the ability to trigger an effective T-cell response is partly determined by the MHC phenotype of the individual and different individuals have different MHC allele (Macdonald *et al.*, 2001; Marrack *et al.*, 2017). The MHC genes are the most polymorphic of all human genes, with more than 10,000 alleles known (as of Feb 2018), and are important in increasing the range of responses that different individuals can mount. In humans, this polymorphism results from concentrated amino acid substitutions in the peptide-binding groove of human leukocyte antigen (HLA, the human MHC system) molecules that produce variability in peptide binding and presentation to T cells (MacDonald *et al.*, 2000). Over the years, few groups have investigated the possibility of a functional classification of HLA polymorphism based on peptide-binding specificities. It was found that majority of HLA alleles (both class I and II) could be grouped into 18 or more different 'supertypes', purely on the basis of similarities in their peptide binding specificity (Lund *et al.*, 2004). It has been suggested that the majority of all major human populations can be covered by only few HLA supertypes, where the different members of each supertype bind similar peptides ('promiscuous peptides') for presentation to T-cell (Sette *et al.*, 1999). Further, latest developments show evidence for presence of "immunological hot-spots" (Srinivasan *et al.*, 2004) in antigens. Immunological hot-spots are defined as antigenic regions possessing multiple promiscuous peptides that are supertype specific. This area of research raises the prospect of identifying key pathogenic antigens that possess immunological hot-spots as best candidates for vaccine design as it will provide protection at the population level, irrespective of ethnicity.

The humoral response involves antibodies produced by B-cells, which recognize both linear and conformational B-cell epitopes on the surface of the pathogen. Conformational neutralizing epitopes are the primary focus of various vaccine research for protective humoral responses. However, unlike linear B-cell epitopes and T-cell epitopes, reliable computational tools for prediction of conformational epitopes are limited (Kulkarni-Kale *et al.*, 2005; Zhang *et al.*, 2011).

As for the pathogens, the last decade witnessed the rapid expansion of sequence data at our disposal, stemming from both genomic and proteomic approaches, enabling analysis to map key antigens that are potential targets for protective immune responses. The genomic sequences of a large number of pathogens that threaten public health have been completed or are impending completion. For example, the whole genome of over 7,475 viruses have been sequenced and deposited in the major public database Entrez Genome (see "Relevant Website section"). The data derived from the genome/proteome sequencing and related projects for a particular species of pathogen, such as West Nile Virus, is the missing gap towards the development of vaccines effective against the majority of the variants currently known within that pathogenic species and probably against novel ones that are yet to emerge (Koo *et al.*, 2009). Such vaccines will be much superior to the current generation of vaccines, which are solely based on a single or few antigens providing protection only against certain variants of a pathogen and therefore might elicit too narrow a breadth of response to provide protection from the remaining diverse variants of the same pathogen species (Doolan, 2003).

We have made significant progress in understanding the processes in the host that are involved in mounting an immune response. However, we are still far from having a good understanding of the natural complexity of the pathogens. A good starting point would be by utilizing the pathogens genomic/proteomic data to study their sequence diversity, and identify antigens containing conserved and variable immunological hot-spots. To fully realize the promise of the available datasets for such study, we would require the development of appropriate technologies for systematically converting genomic/proteomic data into protective vaccines. Recently, systematic genome-wide approach to identify the key antigens of a pathogenic species from the numerous variant sequences of the same pathogen have been reported (Dhanda *et al.*, 2017; Rizwan *et al.*, 2017; Goodswen *et al.*, 2014; Vivona *et al.*, 2006; Del Tordello *et al.*, 2016; Maria *et al.*, 2017; Doolan, 2003; Raman *et al.*, 2014; Koo *et al.*, 2009; Khan *et al.*, 2017). The selected key antigens will represent the minimal representative sets of target sequences required to provide immunity against the majority of the existing variants of a particular pathogen species.

Bioinformatics is an inter-disciplinary field that is essential for the analysis and interpretation of complex and large quantity of biological data generated by functional studies and high throughput technologies. It is used to propose the next sets of experiments and, most importantly, to derive better understanding of biological processes. As stated, the number of pathogen sequence data in public databases is increasing rapidly, however, experimental approaches to study this large data pool for the development of immune interventions are time-consuming, costly and almost impractical. Through combination of bioinformatics and experimental approaches, it is possible to select key experiments and help optimize experimental design. Computer algorithms are increasingly used to speed-up the process of knowledge discovery by helping to identify critical experiments for testing hypothesis built upon the result of computational screening. A number of successful examples for application of computer models to study immunological problems have been described in Brusci *et al.* (2005). Such examples illustrate the power of computational approach to complex problems involving potentially vast datasets with potential biases, errors and discrepancies.

A Computational Framework for Vaccine Target Discovery

Reverse vaccinology, a bottom-up genomic approach, has been successfully applied to the development of vaccines against pathogens that were previously not suited to such development (Vernikos, 2008; Rappuoli and Covacci, 2003; Rappuoli, 2001; Del Tordello *et al.*, 2016). The pre-requisite for this approach is the sequence data of the target pathogen, which acts as input to various bioinformatics algorithms for prediction of putative antigens that are likely to be successful vaccine targets. These candidates can then be validated by a small number of key experiments in the lab. The approach has been successfully applied to the development of universal vaccines against group B Streptococcus (Maione *et al.*, 2005) and vaccine candidates against MenB (Pizza *et al.*, 2000), among others (Rappuoli and Covacci, 2003). Reverse vaccinology is a promising method for the high-throughput discovery of candidate vaccine targets that have the potential to mirror the dynamics and antigenic diversity of the target pathogen population, which includes the diversity of the interacting partner, the immune system. However, a big challenge to this end is the need to understand how vaccine developers can cover antigenic diversity and develop a systematic approach to rationally screen pathogen data to select candidate vaccine targets that cover the diversity.

Over the years, a number of bioinformatics pipelines have been designed that predict vaccine candidates both rapidly and efficiently. VacSol (Rizwan *et al.*, 2017), NERVE (Vivona *et al.*, 2006), and Vacceed (Goodswen *et al.*, 2014) are examples of such pipelines for proteomes of bacterial or eukaryotic pathogens and these pipelines are highly configurable and scalable (Zaharieva *et al.*, 2017). They include multiple steps and integrate various algorithms for analysis and comparison. Shortlisted candidate vaccine targets are ranked for prioritization towards experimental validation. These pipelines are expected to improve the vaccine target discovery process.

The general characteristics desired for a candidate vaccine target are (i) highly conserved; (ii) pathogen-specific; (iii) important for structure/function; (iv) immune-relevant; and (v) antigenically similar to circulating strains. Highly conserved targets are less likely to mutate and escape immune recognition. This is particularly so if they are important for structure and function, suggesting a robust historical conservation. High conservation also reduces the possibility of altered-peptide ligand (APL) effect from variant epitopes of the same pathogen species (Sloan-Lancaster and Allen, 1996; Evavold *et al.*, 1993; Rothman, 2004). Variants may also

originate from other pathogens, in particular those that co-circulate or co-infect with the pathogen of interest and if they belong to the same family. In vaccine design, epitopes common to other pathogens could either be useful by inducing cross-protection, or detrimental by inducing altered-ligand effect. Thus, potential vaccine targets should be analyzed for specificity to the target pathogen. The definition of virus species-specific vaccine targets can be further expanded to exclude those with one amino acid mismatch to human sequences in order to avoid possibility of molecular mimicry. Antigenic mismatch between a vaccine and circulating strains has been shown to increase the risk of disease outbreak by 1000-fold compared to immunization using identical strains (Park *et al.*, 2004). Thus, it is important to assess the extent of antigenic identity between the candidate vaccine targets and the circulating strains.

Typically, a generic semi-automated computational framework comprises of three key components: data collection, data processing, and data analysis (Khan, 2005, 2009; Khan *et al.*, 2006, 2017). Fig. 1 illustrates the workflow of the framework and Fig. 2 provides a non-comprehensive list of commonly used tools. Data collection would involve the user providing a set of sequences (aligned or unaligned) of the pathogen of interest for analysis. The sequences could be a single protein dataset, multiple or the complete proteome. Additionally, comparative analyses of the sequences can be performed between subtypes/groups of the pathogen. The sequences can be retrieved from public repositories, primary or specialist databases, such as the NCBI Entrez Protein database (NCBI Resource Coordinators, 2017) or Influenza Research Database (IRD) (Zhang *et al.*, 2017), respectively. User can also provide sequences derived from their experimental work, not available in public databases. Typically, downloaded data would comprise full-length or partial sequences, and the corresponding metadata. Data processing would involve removal of duplicate sequences from the dataset, and for comparative analysis, the merging of the input sequences will be required prior to the alignment step. Multiple sequence alignment will be carried out using an existing tool that is robust in dealing with large sequence data, such as (Sievers *et al.*, 2011; Katoh *et al.*, 2017; Edgar, 2004; Do *et al.*, 2005) Clustal Omega, MAFFT, MUSCLE or PROBCONS. The output alignment quality will be manually inspected for any errors and/or misalignments, which are common when dealing with partial sequences. Henceforth, the data would be ready for analyses, which can involve performing a diversity analysis, such as by measuring entropy values (Heiny *et al.*, 2007; Hu *et al.*, 2013; Khan *et al.*, 2008; Koo *et al.*, 2009) and quantifying variant motifs for each, user-defined, k-mer positions in the alignment. The results of these analyses will be plotted as an output for the user, providing a holistic view of the diversity, including variant distribution. The user can define a preferred conservation threshold for selection of highly conserved sequences. These selected sequences are then analyzed for distribution of variants in nature (Khan *et al.*, 2008; Koo *et al.*, 2009), including matches to human proteins, enabling the identification of pathogen specific, highly conserved sequences. The robust nature of the historical conservation can be assessed by performing functional and structural analysis (Sprenger *et al.*, 2008; Hung and Link, 2011; Wizemann *et al.*, 1999; Sachdeva *et al.*, 2005; Monterrubio-López *et al.*, 2015; He, 2014; Tang *et al.*, 2014; Maria *et al.*, 2017). The relevance of the identified potential candidate vaccine targets for use against current circulating strains can be assessed by measuring the incidence of the candidate targets in the corresponding sequences of recent strains of the virus of interest (Khan *et al.*, 2017). The antigenicity/immunogenicity of the candidate sequences are predicted to assess their immune relevance. Experimental validation includes matching the predicted epitopes with reported epitopes in public databases, such as the Immune Epitope Database (IEDB) or SYFPEITHI, or performing quantitative measurements of the pre-selected candidate peptides by generating synthetic constructs and testing for their immunogenicity, such as by use of HLA transgenic animal models that express specific HLA alleles (Rosloniec *et al.*, 1997; Lefranc *et al.*, 2009; Gourlay *et al.*, 2017; Khan, 2005).

Immunoinformatics

Bioinformatics tools can facilitate the process of epitope mapping by identifying peptides that can potentially elicit T-cell responses. Binding of epitopes to HLA antigens is highly allele-specific; core peptide-binding motifs (usually between 8- and 11-mers, most often 9-mers) have been defined experimentally for a number of HLA class I and class II alleles and incorporated into computational algorithms, allowing to predict candidate HLA-binding epitopes *in silico* from protein sequences (Parker *et al.*, 1994; Rammensee *et al.*, 1999; Sturmiolo *et al.*, 1999; Zhang *et al.*, 2005; Nielsen *et al.*, 2010; Karosiene *et al.*, 2013; Paul *et al.*, 2013, 2015a,b; Andreatta *et al.*, 2015; Andreatta and Nielsen, 2015; Pro *et al.*, 2015; Trolle *et al.*, 2015; Abelin *et al.*, 2017; Jurtz *et al.*, 2017; Fleri *et al.*, 2017). More recently, quantifiable predictive features of TCR $\alpha\beta$ binding to HLA/epitope complexes have been also described (Birnbaum *et al.*, 2014; Dash *et al.*, 2017; Glanville *et al.*, 2017; Gee *et al.*, 2017).

Two main categories of specialized immunoinformatics tools are available for prediction of MHC binding peptides – methods based on identifying patterns in sequences of binding peptides, and those that employ three-dimensional (3D) structures to model peptide/MHC interactions (Tong *et al.*, 2007; Liljeroos *et al.*, 2015; Gourlay *et al.*, 2017). Pattern-based methods includes binding motifs, quantitative matrices, decision trees, artificial neural networks (ANNs), hidden Markov models (HMMs) and support vector machines (SVMs), among others. In contrast, the structure based methods are theoretically rooted and include homology modeling, docking and 3D threading techniques (Dominguez *et al.*, 2003; De Vries *et al.*, 2010; Agostino *et al.*, 2016; Khan and Ranganathan, 2010; Liljeroos *et al.*, 2015; Gourlay *et al.*, 2017). Although less accurate, pattern based approaches are over-represented in the literature due to higher complexity in development and longer computational time of the more accurate structure-based approaches (Ranganathan and Tong, 2007; Maria *et al.*, 2017), including the sheer difference in the availability of linear versus structural data.

For a given sequence, typically all possible overlapping 9-mer (and later, 8- to 11- mer) peptide sequences are extracted. Epitope prediction for HLA class I and class II alleles are performed using benchmarked prediction models, including, for HLA

Fig. 1 Computational framework for vaccine target discovery.

class I epitopes, the artificial neural network (ANN)-trained NetMHCpan (version 4.0) (Andreatta *et al.*, 2015; Trolle *et al.*, 2015; Jurtz *et al.*, 2017), and for HLA class II epitopes, NetMHCIIpan (Karosiene *et al.*, 2013; Andreatta and Nielsen, 2015), and the allele-specific consensus percentile ranks of all algorithms queried by the Immune Epitope Database and Analysis Resource (IEDB) tools (combination of NN-align, SMM-align, and ComLib/Sturniolo) (Paul *et al.*, 2015a,b). Additionally, proteasome cleavage (Hakenberg *et al.*, 2003; Nussbaum *et al.*, 2001; Nielsen *et al.*, 2005) and TAP binding predictions (Zhang *et al.*, 2006; Bhasin *et al.*, 2007; Bhasin and Raghava, 2004) will be performed for priority ranking. Several tools, such as NetCTL (Larsen *et al.*, 2005), integrate these various predictions into one and predict for HLA supertypes, which are groups of HLA alleles with similar peptide

Fig. 2 An example of commonly used tools and databases for vaccine target discovery.

binding specificity. Potentially cross-reactive self epitopes may be searched within the human proteome using BLAST/BLAT alignment tools (Kent, 2002; Altschul *et al.*, 1990).

Case Studies: Vaccine on Infectious Diseases and Non-Infectious Diseases

Infectious Diseases

Reverse vaccinology immunoinformatics approaches are widely applied for viral vaccine design, such as for influenza virus, chikungunya virus, zika virus and others (Gupta *et al.*, 2016; María *et al.*, 2017), including parasites (Damfo *et al.*, 2017) and bacteria (Mistry and Flower, 2017; Zahroh *et al.*, 2016; Rappuoli, 2001). Khan *et al.* developed a bioinformatics pipeline for DENV, which proved generic as it was successfully applied to several viruses, such as WNV (Koo *et al.*, 2009), a close relative of DENV (Khan *et al.*, 2008), and a number of other viruses, such as HIV-1 (Hu *et al.*, 2013), among others. It provides a novel and generalized approach to the formulation of peptide-based vaccines targeting a broad diversity of pathogens and applicable to the human population at large. This methodology is a significant contribution to the field of reverse vaccinology as it enables the systematic screening and analyses of pathogen data which would otherwise be impossible to carry out experimentally, due to too many pathogen sequences (high viral diversity) and variations in immune system among individuals (extensive polymorphism of HLA). This approach therefore significantly reduces the efforts and cost of experimentation, while providing for systematic screening and analyses of pathogen proteomes (Raman *et al.*, 2014).

Khan *et al.* (2008), Koo *et al.* (2009) and Hu *et al.* (2013) analyzed a large number of dengue (DENV), West Nile virus (WNV) and clade B HIV-1, sequences, respectively, retrieved from the NCBI Entrez protein database (Table 1). The sequences were aligned and the overlapping nonamer amino acid positions of the viral proteome, each a possible core binding domain for human leukocyte antigen molecules and T-cell receptors, were quantitatively analyzed. The mean entropy of DENV nonamer sequences was low, with a range of 0.2–1.0 for within and 1.6–2.6 for between serotypes. This was even lower for WNV, ranging from 0.2–0.5, with the highest for HIV-1 clade B subtype, 1.9–4.2. Entropy is a general measure of diversity, and the data provided a holistic overview viral diversity across the proteome. Accordingly, the incidence of variants to the most prevalent, index sequence at the aligned nonamer positions was the lowest for WNV (intra: $\leq 10\%$) and the highest for HIV-1 clade B (intra: $\sim 80\%$ – 99%); the variants incidence within each DENV serotype was comparable to WNV, but between serotypes ($\sim 60\%$ – 80%) was closer to HIV-1 clade B subtype. Forty-four (44) sequences (pan-DENV sequences) identical in 80% or more of all recorded DENV sequences represented 15% of the DENV polyprotein length. The proportion (34%) was much higher for WNV and at complete conservation (100% incidence). Notably, at similar incidence level ($\geq 80\%$ incidence) to DENV, although pan-clade, $\sim 35\%$ of the intra HIV-1 clade B proteome was highly conserved. The proportion of these conserved sequences that were immune-relevant showed an inverse relationship: DENV (59% matched 9aa or more of 45 class I and II reported epitopes), WNV (50% matched 9aa or more of 57 class I and II reported epitopes), and HIV-1 clade B (37% matched 9aa or more of 73 class I and II reported epitopes). Khan *et al.* (2008) highlighted that conservation analysis should go beyond the species of interest, extending to all those

Table 1 Key summary results of vaccine target discovery study on Dengue virus (DENV), West Nile virus (WNV) and clade B HIV-1.

Category	DENV (Khan <i>et al.</i> , 2008)	WNV (Koo <i>et al.</i> , 2009)	HIV-1 clade B (Hu <i>et al.</i> , 2013)
Mean nonamer entropy	Intra: 0.2–1.0 Inter: 1.6–2.6	Intra: 0.23–0.51	Intra: 1.9–4.2
General variants incidence trend	Inter: ~60%–80%	Intra: <10%	Intra: ~80%–99%
% of the proteome covered by conserved sequences	Pan-clade: 15% (>=80% incidence)	Intra: 34% (=100% incidence)	Intra: 35% (>=80% incidence)
Immune relevance	(26/44) 59% matched 9aa or more of 45 class I and II reported epitopes	(44/88) 50% matched 9aa or more of 57 class I and II reported epitopes	(29/78) 37% matched 9aa or more of 73 class I and II reported epitopes
No. of other viral species matched by the conserved sequences	(27/44) 61% matched 64 flaviviruses	(67/88) 76% of the sequences matched 68 flaviviruses	(74/78) 95% matched 9 deltaviruses
No. of pathogen specific conserved sequences	17	21	4

other species that are evolutionarily related as they may act as variants to the conserved epitopes identified. This step is necessary to identify conserved epitope sequences that are pathogen specific, with none or minimal number of variant sequences within or across other pathogen species. Variant epitopes are hypothesized to cause deleterious immune responses. Many of the conserved sequences matched nine consecutive amino acids of many (flaviviruses; family of WNV and DENV) to few (*deltaviruses*; genus of HIV-1) other related viruses, leaving only 17, 21 and 4 pathogen specific conserved sequences for DENV, WNV and HIV-1 clade B subtype, respectively.

Non-Infectious Diseases

According to World Health Organization (WHO), non-infectious diseases, especially chronic diseases will lead the disability by 2020. Hence, diseases such as cancers, obesity, neurodegenerative disease addictions and others have become a recent focus of vaccine development (Barrett, 2016). Cancer is the most common non-infectious disease that leads death world-wide. Due to the advanced technology and success of *in silico* methods in infectious disease vaccine design, computational approaches have been applied in study of cancer vaccine design. For example, VacImm was developed as a bioinformatics approach to simulate peptide vaccination in cancer therapy (von Eichborn *et al.*, 2013). In addition, modeling approaches using computational biology, such as Sim Triplex and MetastaSim model are important to understand the molecular interactions at the cellular and molecular level (Pappalardo *et al.*, 2013; Sankar *et al.*, 2013). Adekiya *et al.* (2017) reports a recent example of a study that included bioinformatics analysis in cancer vaccine development.

Conclusion: Vaccine Informatics and Future Vaccines

Future vaccines will be minimalistic in approach by focusing on key parts of the pathogen, such as regions containing epitopes that cover antigenic diversity and, thus, will target immunologically similar subgroups of the human population and multiple pathogen variants. This is evident from the trend observed in evolution of vaccine strategies, which has seen a shift from whole organisms to recombinant proteins, and further towards the ultimate in minimalist vaccinology, the peptide/epitope/multi-epitope based vaccines. The minimalist approach is also expected to cover the safety concerns that are associated with the traditional vaccine approach of using whole organism (Sette and Fikes, 2003; Dertzbaugh, 1998). Vectored vaccines, suitable for 'combination immunization' that are produced by recombinant DNA technology and contain multivalent minimal antigens to protect against multiple infections, are considered to be the future of vaccinology (Kutzler and Weiner, 2008). The future will bring increased integration of vaccine research with advances in immunology, molecular biology, genomics, proteomics, informatics, and high-throughput instrumentation, collectively defined as the emerging field of "vaccinomics", which is hailed to be responsible for the next 'golden age' in vaccinology (Poland *et al.*, 2008). Awareness of the novel technological possibilities in vaccine research is also expected to grow. Future vaccinology will be based on detailed understanding of immune function, optimal stimulation of immune responses (using adjuvants) and precise mapping and rational selection of immune targets (Brusic *et al.*, 2005). To achieve this, vaccine development will routinely be conducted through large-scale functional studies supported by genomics, proteomics, and informatics techniques prior to clinical trials. This will provide an increased range of immune targets for vaccine design. The author expects the emergence of new generation of vaccines to be personalised to both the genetic make-up of the human population and of the disease agents. In summary, vaccinology will experience rapid progress and will eventually deliver benefits to patients from improved diagnosis, treatment and prevention of diseases.

Biographical Sketch

Chong Li Chuin is a Biomedical Science undergraduate student from Faculty of Medicine and Health Sciences, UPM. As part of her undergraduate studies, she completed an internship at Perdana University Centre for Bioinformatics (PU-CBi), Malaysia. She continued to be involved with the Centre to build on her passion for bioinformatics.

Associate Professor Dr. Mohammad Asif Khan is currently the Dean of the Perdana University School of Data Sciences, the Director of Perdana University Centre for Bioinformatics (PU-CBi), Malaysia, and a Visiting Scientist at Johns Hopkins University School of Medicine (JHUSOM), USA. He obtained his PhD in Bioinformatics from the National University of Singapore (NUS), and did his postdoctoral fellowships at NUS and JHUSOM. Dr. Khan's research interests are in the area of biological data warehousing and applications of bioinformatics to the study of immune responses, vaccines, venom toxins, drug design, and disease biomarkers.

Protocol for Protein Structure Modelling

Introduction

Protein structure has four levels of organization. The primary structure is represented by sequence of amino acids bound together by peptide bonds. When backbone atoms of one amino acid residue make hydrogen bonds with the backbone atoms of other residues, α -helices and β -pleated sheets are formed that comprise the secondary structure of a protein. These secondary structural elements are connected by loop regions. The folding of secondary structure elements into 3-dimensional (3D) space yields tertiary structure of a protein. In some proteins, folded chains of more than one polypeptide interact with each other to form quaternary structure. Protein structure dictates its function (Voet *et al.*, 2016). Mutations that alter the structure of a protein can lead to alteration of function which can either be detrimental or beneficial, therefore a thorough understanding of protein structure is mandatory to have insight into the biology of life (Starr *et al.*, 2011). Moreover, a 3D structure serves as an important starting point for insights into essential features of an evolutionary protein family, thereby establishing a possibility of identification of even remotely related proteins through structural similarities (Lacapere, 2017).

Protein structures that are determined through experimental methodologies (primarily by X-ray crystallography (XRC), nuclear magnetic resonance spectroscopy (NMR) and electron microscopy) are often submitted to the Protein databank (PDB) which is the largest repository for experimentally determined structures of proteins, nucleic acids and other complex assemblies (Berman *et al.*, 2000). There are numerous derived databases representing PDB files for specific families of proteins and their related information: for instance, PDBTM has transmembrane proteins selection of PDB (Kozma *et al.*, 2012).

Despite the rapid increase in the percentage of structures determined from different experimental methods (Table 1), there is still a vast gap between protein sequence (99,261,416 UniProt entries as on December 2017) and structure (125,799 protein PDB entries as on December 2017) entries. Some classes of proteins are significantly under-represented in the PDB: for instance, membrane proteins represent 40% of the human proteome (Lacapere, 2017) but only 702 structures (as on July 2017) have been solved experimentally. This is primarily due to the difficulty in crystallizing these proteins. Olfactory receptors, which represent the largest family of G protein coupled receptors (GPCRs) do not have a single experimentally solved structure. The lack of solved structures of proteins have long been recognized as a bottleneck in rational drug design; for instance, casein kinase II (CK2) has been extensively studied due to its implications in cancer, with potential inhibitors searched by testing against CK2. The CK2 XRC structure (PDB ID: 3AT2) has paved the way for discovery and optimization of its inhibitors through structure-based drug designing (Cozza, 2017).

Computational approaches can be used to predict the structure of the protein at a fraction of the cost and time compared to the experimental methods. Though these methods are not as accurate as experimental methods, the quality and efficiency of structure prediction in the past few years has demonstrated that it can be a viable complement to experimental methods (Khor *et al.*, 2015). The majority of structure-prediction methods provide structural templates closely matching the query protein sequence. This article provides the protocol for structure prediction of a protein through template-based modelling, with the basic aim of providing practical guide to readers to use computational approaches for structure prediction.

Methods for Protein Structure Prediction

Protein structure prediction is the method of inference of protein's 3D structure from its amino acid sequence through the use of computational algorithms. The 3D structure of a protein is predicted on the basis of two principles; the laws of physics and evolution. According to physical principles, protein folds into a stable and well-formed structure by minimizing the energy, while according to evolutionary principles, a protein molecule is a consequence of gradual changes in sequence and structure over the

Table 1 Experimental methods for protein entries in the Protein Databank

^aAs on 4 September 2017.

course of time. These two principles set up the foundation of the two protein structure prediction methods that are template-based modelling (homology modelling and threading method) and template free modelling (*ab initio* modelling), respectively (Illergård *et al.*, 2009). Hybrid methods utilize both of these methods. The selection of the methods depends primarily upon the availability of the templates structures in PDB.

Protein structure prediction took its ground with the thermodynamics hypothesis proposed by an American biochemist Christian Anfinsen in 1962. This hypothesis was based on his work conducted in 1954 on folding of bovine pancreatic ribonuclease into 3D conformation, i.e., native conformation (Anfinsen *et al.*, 1954), and then in 1961 he reported refolding of unfolded bovine pancreatic ribonuclease A into its native conformation (Scheraga, 2014). During the Anfinsen's Nobel acceptance speech in 1972 he talked about the dependence of 3D conformation upon amino acid sequence, which motivated different groups to work on protein structure prediction problem. One of the earliest efforts was done by Gibson and Scheraga in 1967 in finding thermodynamically stable conformation of protein by using different computer searching techniques (Wooley and Ye, 2007). The first success in the area of protein fold prediction from its amino acid sequence came in 1975 when Levitt and Warshel folded bovine pancreatic trypsin inhibitor (58 residues long) using energy minimization. In 1969 Browne and his co-workers exploited the observation that proteins that share sequence similarities share similar structure, to predict the structure of α -lactalbumin using the X-ray structure of lysozyme as a template, and this laid the foundation for comparative modelling (Guo *et al.*, 2008). After the prediction of the first homology model, continuous improvements have been made, from semi-automated to fully automated homology modelling. Homology (Greer, 1981) was the first semi-automated program and Modeller (Šali and Blundell, 1993) was the first fully automated program. The first ever fully automated server with web interface was then built in 1993, named SWISS-MODEL (Guex *et al.*, 2009). Great number of programs and fully automated servers are now available for solving protein structure prediction problem.

To bridge the gap between protein sequences and structures and to encourage the development of fast, efficient and accurate structure prediction methods, a community-wide global protein structure prediction experiment known as the Critical Assessment of protein Structure Prediction, or CASP was started in 1994, with the sequences of protein structures about to be experimentally solved offered as targets for prediction. Participants then submit their predicted models which are then compared to experimentally determined structures (Moult *et al.*, 2016). The main classes of protein structure prediction methods are briefly described below.

Homology Modelling

Homology modelling has proven to be the most successful approach for protein structure prediction but it requires that a template exists in PDB (Fiser, 2010), such that, the better the template, the more accurate the prediction. This approach is greatly benefited by the fact that structure of at least one member of almost all the families of proteins have been deduced experimentally which can be used as a template for modelling the other members of that particular family (Song *et al.*, 2013).

Threading

Threading relies on the observation that a limited number of folds are present in nature due to which even remotely homologous proteins have similar structures (Kelley and Sternberg, 2009). Protein threading methods are based on a *Z-score* which tests the possibility of target protein sequence to fold in the structure that is similar to the template structure. The *Z-score* represents the distance between optimal alignment score and mean alignment score that is obtained by random shuffling of a target sequence. This method involves building up databases for representative, non-redundant template structures, followed by devising a fitness scoring function which is based on the knowledge of known sequence to structure relationships. The scoring function is then minimized by finding the optimal alignment between the target and template and in the end, best template is selected based on all the template sequence alignments (Markstein and Xu, 2006).

Ab initio Methods

When a matching template cannot be found for a query sequence by use of homology or threading approaches, the *ab initio* methods are used to model the structure. These template-free methods rely on a set of core principles that are based on folding energetics and statistical tendencies of conformational characteristics demonstrated by experimental structures (Lee *et al.*, 2017). The general steps include devising an accurate energy function to estimate which model structures are thermodynamically stable, using an efficient search method that can identify lowest energy conformations, and selecting the near native conformation from a pool of structure decoys.

Ab initio methods are the least accurate of all the structure prediction methods and have limitations of protein size, and therefore is only used to model smaller proteins/peptides (Lee *et al.*, 2017).

Over the past decade substantial improvement has been made in the performance of different protein structure prediction servers. Table 2 lists the top ten automated structure prediction servers according to the recent CASP 12 ranking.

Table 2 Top 10 automated structure prediction servers according to CASP 12 ranking^a

Once a 3D structure for a protein sequence has been predicted using any of the three methods described above, the quality of the predicted structure needs to be thoroughly checked. CASP has been instrumental in developing methods for evaluating the quality and accuracy of structural models (Schwede, 2013).

Given a protein sequence with unknown structure, predicting its 3D structure is a laborious task, especially due to continuous improvements in structural knowledge and prediction methods as a result of advances in the area of structural bioinformatics. We present a comprehensive protocol for structure modelling, exemplified by a case study.

Protocol for Protein Structure Modelling

Given a protein sequence with unknown structure, the following protocol can be used to predict its 3D structure (Fig. 1), with each step elaborated in the following sub-sections.

Preliminary Step: Sequence Analysis

Analyzing the target sequence assists in providing useful biological information which can be further utilized in template selection and sequence alignment. The features that can be examined within the target sequence are as follows:

Protein family analysis

It has been established that two protein sequences of a length of over 100 amino acids that share more than 30% identity are predicted to have a similar structure and function (Pearson, 2013). Such proteins are called homologues (“siblings”) and are assumed to have evolved from a common ancestor. When the sequence identity between two proteins is within and below 20%–35%, they fall in the twilight (“cousins”) zone (Bahar *et al.*, 2017). The structure relatedness is not obvious from sequence relationship in this case and therefore can be inferred from structural alignment. Structure is three to 10 times more conserved than sequence because amino acid changes in the primary sequence are reflected in the structure in terms of type and location of the changes in 3D space. Even a single amino acid mutation could affect the structure completely, but if physicochemical properties remain conserved, the structure remains unaffected (Illergård *et al.*, 2009). For example, haemoglobin from a trematode which binds and transports oxygen (PDB: 1H97) has only 12.1% sequence identity with the haemoglobin of an annelid (PDB: 2GTL), which is part of a larger protein, erythrocrutorin (3.6 million Da) and performs other functions in addition to binding and transporting oxygen. However, both share similar structures (RMSD: 2.3 Å), are part of the globin-like superfamily and have similar function (Sousounis *et al.*, 2012). Despite the low sequence identity, proteins with a similar structure and function have remarkable conservation in the active site residues such that if an accurate model of the active site can be obtained, it can be utilized to elucidate the protein’s function and ligands.

Conservation of residues important for structure and function

The function of a protein depends on the localization in space of a few key residues that are conserved through evolution and occupy identical positions in corresponding structures, usually in a solvent accessible cavity. Some residues are important for the stability of the protein fold or for formation of quaternary structures. If a protein contains buried charged residues that are conserved among homologues, such residues are also usually important for maintaining function (Isom and Dohlman, 2015).

Motifs and patterns

Identification of patterns and motifs can be done through databases (listed in Section Useful Resources) and literature searches. These patterns can then be mapped onto a template to have optimal alignment (Taylor, 1992).

Domain analysis

Protein domains represent the autonomously folding functional units of a protein, which can be present as a repeated unit or in combination with other domains (Marchler-Bauer *et al.*, 2012). Protein sequence of length greater than 150 must be checked for the occurrence of multiple domains.

Template Identification

Template structure defines the framework for 3D structure prediction of a target protein. Templates are identified by aligning the target (query) sequence with sequences of available structures in PDB. The three available methods for template identification by alignment are summarized in Table 3.

Sequence-based methods are more specific but less sensitive than profile-based methods, which are more sensitive but less specific than structure-based methods. Basic Local Alignment Search Tool (BLAST) search results give clues of templates and region of high similarity but for model building we must align the target and template sequences globally. Every domain of the query protein must have a template to model it. If for any domain a template does not exist, it cannot be modelled by homology or comparative modelling. Homologue identification can be improved by splitting the long sequences into domains as determined by comparison with domain databases, and then searching a homologue for each domain.

Criteria for defining a homologue

The following parameters should be considered while defining the homology between two proteins:

Table 3 Methods for template identification

Alignment methodology	Description	Example
Sequence-based	Suitable for high identity	Protein BLAST
Profile-based	Suitable twilight-zone proteins	psi-BLAST, SAM, HHSEARCH, FFAS
Structure-based	Incorporates structural features for instance, secondary structure and solvent accessibility	RAPTOR, SPARKS, MUSTER, LOMETS

1. Alignment score and e-value: high alignment scores and low e-values (rule of thumb: <0.005) are usually desired.
2. Domain coverage: the aligned region between the two proteins must cover at least 60% of the structural domain involved.
3. Gaps: fewer gaps are better as they result in a higher quality model. Long and contiguous insertion/deletion ("indels") regions are preferred to several short indels, for generating a better structural model. Templates with fewer gaps and reasonable similarity scores are preferred over the templates with high scores and but too many gaps.

Template identification for small proteins

Small proteins lack a hydrophobic core and are stabilized by disulphide bridges, between cysteine side chains (Thangudu *et al.*, 2008) or by binding metal ions. Thus, while identifying templates for small proteins, the conservation should be restricted to the cysteine residues involved in making the disulphide bridges, and to residues that are involved in binding metal ions without which the proteins would not be able to fold properly. The size of the loops between the conserved cysteine residues is also crucial as gaps in such regions can affect the predicted model. The right modelling approach for small proteins must be able to produce a model with disulphide bridges or metal ions present intact, to make it biologically relevant.

Targets without homologues

If no considerable homologue is retrieved for the target by any of above tools, then its secondary structure can be predicted, which can give clues about class of the protein and order of occurrence of secondary structure elements that can then be used for matching with a fold, predicted by fold recognition methods (Section Useful Resources). If this also does not help, then *ab initio* methods can be used for model building. The regions of target sequence which does not have any template can be built up using an *ab initio* approach.

Template Selection

If only one template is identified, then model should be built with this template, otherwise appropriate template(s) may be selected from the pools of templates. For selection of templates a number of factors need to be considered, which include:

Sequence similarity

Multiple sequence alignment of all the domains of potential templates and target sequence can be performed and utilized in building a phylogenetic tree which can then depict the most similar structure that can be used for model building.

Similarity in secondary structure

A template with similar secondary structure as the predicted secondary structure of the target can be prioritised.

Bounded ligands

If the ultimate goal of structure prediction is receptor and ligand interactions studies, then a template that has the same binding ligand (if any) as of the protein of interest should be preferred.

Resolution of template structure

High resolution XRC structures are preferred over low resolution structures. Similarly, XRC structures are preferred over NMR. But if only NMR structures are available, the "average" NMR structure must be chosen for model building as NMR protein structures are often submitted in PDB as ensembles of models.

Presence of missing residues

Missing residues (if any) information is present in REMARK 465 in the header section of a PDB file. Missing residues information can also be seen by using most PDB viewer. If missing residues are present, then an alternate template should be selected, otherwise more than one template should be used to fill in the gaps. If the ultimate goal of structure prediction is to study protein interactions, then no missing residues should be present in the binding sites of the template.

Multiple templates

Optimal use of multiple templates can increase the accuracy of the developed model. If every template is providing unique information and there are minimal overlapping residues between templates, they can be selected for building a model. Superimposing C α atoms can reveal the unique information each template is contributing. Other features to look at are insertions, variation in the length of secondary structure elements and different conformational loops. Few of the programs can build model by using multiple templates like Modeller, IntFOLD and M4T (Fiser, 2010). If sequence identity falls below 40%, multiple template usage is favorable but above this identity a single template will usually suffice (Fiser, 2010).

Target-Template Alignment

The most crucial task in modelling that guides the model building and determines the quality of a model is target to template alignment. When sequence identity between target and template drops below 40%, accurate alignment is critical. Incorrect alignment of even a single residue can result in error of approximately 4 Å in the resulting model (Fiser, 2010).

For optimal alignment, the profile of target sequence can be generated by aligning it with its close homologues through multiple sequence alignment (MSA) through any MSA tool like T-COFFEE or ClustalW, which can show the conserved and variable parts of the target sequence. As structure-based alignment is more significant than sequence-based alignment, it is good to align all the selected templates structurally by using UCSF Chimera. Structure-based sequence alignment (SSA) can then be extracted from already aligned structures in UCSF Chimera and aligned with multiple sequence alignment (MSA) of target sequence using profile alignment without any modification of alignment within SSA or MSA. The target-template alignment can now be extracted from this profile. The following checks must be performed to improve the quality of the alignment.

Residue conservation

- Analysis of positions of identical and similar residues in terms of chemical similarity, charge, size and nature.
- Presence of functional regions, motifs and patterns must be analyzed preferably by mapping available experimental information.
- Histidine-rich sites often binds metal ions that are necessary for proper folding of small proteins (Section Template identification for small proteins) while proline has a structural role in guiding the protein folding. Therefore, the conservation of cysteine, proline and histidine residues must be checked for small proteins.

Gaps in alignment

Small gaps (indels) separating few residues should be combined into a long gap. Different sequence alignment methods (e.g., T-COFFEE or ClustalW) can provide clues regarding aggregation of gaps.

Gaps in secondary structures

If there are any indels present within α -helices or β -strands, they must be moved to the closest loop. Indels are normally placed at the end of the loop where the backbone is turning around to have a better quality model. These indels can be mapped onto the template by visualizing through any PDB viewer.

If multiple templates are chosen, then they all must be superimposed for structure alignment using any structure alignment tool such as UCSF Chimera. Structure-based sequence alignment can be extracted and can be used for model building, this alignment is different from sequence based alignment and provides improved results especially in case of low homology. Final target-template alignment is then passed to the next step of model construction.

Model Building

A number of tools are available for constructing a model on the basis of target-template alignment. Table 4 summarizes the features of different programs used for modelling. Programs such as Modeller and I-TASSER provide a model refinement feature, in addition to model building. Others like WhatIF and MOE include the structure validation feature as well. Numerous webserver are also there that take in query sequence as an input and pass it through a pipeline of different programs for template identification, sequence alignment, model building, structure validation and refinement. The webserver used for automated structure prediction are summarized in Table 5. The most popular ones are I-TASSER, Robetta and Swiss model. A few servers such as I-TASSER and Swiss model even allow the user to select the template of their choice. Webserver like Bhageerath-H follow a hybrid approach of modelling, i.e., modelling is based on a template but if template is not spanning the query sequence somewhere, *ab initio* modelling will then be used to provide a complete model.

Structure Quality Analysis

It is essential to first evaluate the quality of the predicted model before using it for further analysis. The main features of the predicted model that can be assessed include bond lengths, bond angles, torsion angles, atomic clashes, distribution of hydrophobic and polar residues (Feig, 2016). Numerous webserver and tools are available to validate the protein structural model (Table 6). Each server validates different features like stereo-chemical correctness or knowledge-based statistical measures that have been derived from experimentally solved high resolution structures and has defined threshold for validation of the model (Schwede, 2013). For instance, the PSVS server calculates *Z-score* for protein structure validation that is based on a set of 252 X-ray structures <500 residues, of resolution ≤ 1.80 Å, R-factor ≤ 0.25 and R-free ≤ 0.28 and models with positive scores are considered as good models. Many webserver also integrate several tools into one platform, such as protein structure analysis and validation (ProTSAV) and protein structure validation software suite (PSVS). To evaluate the performance of quality validation tools, quality validation category was introduced in CASP7 and from then onwards performance of quality validation servers have been evaluated in CASP every 2 years (McGuffin *et al.*, 2013).

Table 4 Programs available for protein structure modelling

Method	OS	Freely available	Single/multiple templates	Method used	Key features
Modeller Webb and Sali (2014)	Windows, Mac, UNIX/Linux	Free for academia	Both	Modelling by satisfaction of spatial restraints	1. Most frequently used 2. Protein sequences and/or structures comparison 3. Clustering of proteins 4. Sequence databases searching 5. Model refinement 6. Model Loops
WHATIF Vriend (1990)	Windows, Linux	No	Single	CONCOORD (generation of geometric bonds from template and modelling on the basis of geometric bonds) Global optimization	1. Display, manipulate and analyze small molecules, proteins, nucleic acids, and their interactions. 2. Cannot model indels 3. Structure validation
ICM Abagyan <i>et al.</i> (1994)	Windows, Mac, UNIX/Linux	Under academic licence	Single		1. Interface for molecular modelling, fully-flexible ligand and receptor docking, virtual ligand screening
MOE Molecular Operating Environment (MOE) (2017)	Windows, Mac, Linux	No	Both	Segment matching procedure (Levitt, 1992)	1. Highly interactive 2. Homology detection 3. Structure- based alignment facility 4. Side chain and loop modelling 5. Structure validation
I-TASSER Yang <i>et al.</i> (2015)	Linux	Free for academia	Both	Replica-exchange Monte-Carlo simulation technique	1. Integrated package for protein structure and function prediction 2. Use multiple threading technique to identify template 3. Model refinement
Nest Petrey <i>et al.</i> (2003)	Linux	Free for academia	Both	Artificial evolution algorithm	1. Side chain modelling 2. Loop modelling 3. Rapid model building

Table 5 Webservers available for protein structure modelling

Server	Domain boundary prediction	Template identification	Method for Sequence-template alignment	Method for model generation	Model refinement	Quality assessment
I-TASSER Zhang (2008)	Built-in process	LOMETS (User can also provide template) v	PPA Decoy-based optimized potential	Replica-exchange Monte carlo simulation technique	REMO	C-score ^a
Robetta Chivian <i>et al.</i> (2003)	Ginzu	BLAST, Psi-BLAST, FFAS03 and 3o-Jury	K*Sync	Rosetta fragment-insertion technique ¹	–	DISOPRED

Structure Refinement

Structure refinement is based on the quality report. The goal of refinement is to improve the predicted model in a way that it has accurate side chain orientations and high stereo-chemical quality so that it might get closer to the native structure (Carlsen and Røgen, 2015). The following are two strategies used for structure refinement:

Potential energy minimization and molecular dynamics

Potential energy minimization (PEM) techniques are used to eliminate high energies in the predicted model and achieve local minima that is closer to native structure. Molecular dynamics (MD) is comparatively computationally expensive among all refinement techniques, but it is the most prevalent strategy for refinement (Feig, 2017). FG-MD (Zhang *et al.*, 2011) is one of the examples of MD-based refinement server.

Structure optimization

Poor quality regions reported by quality checks can specifically be targeted and optimized iteratively to improve the model. Secondary structure elements and hydrogen bonding networks can be optimized. One example of refinement method using structure optimization approach and energy minimization is 3DRefine (Bhattacharya and Cheng, 2013). Editing target-template alignment and rebuilding a model iteratively can often improve the built model. Structure optimization after the MD is more useful for improving overall quality of the fold (Feig, 2017).

Success Stories of Protein Structure Modelling

Protein structure prediction methods are successfully bridging up the sequence-structure gaps by complementing experimental methods. Few examples of successful model predictions are given below to show how these methods are revolutionizing the research in structural biology.

Homology Modelling Using a Single Template

A structural model for DORN1 (plant purinoreceptor) was predicted through homology modelling (Tanaka *et al.*, 2016) and used to predict the extracellular ATP (eATP) binding pocket in DORN1, and key residues involved in binding. Blind docking and different tools for ligand pocket prediction were then used to predict the eATP binding pocket in the predicted model. Predicted binding pocket was then validated by site directed mutagenesis of key residues. Results showed the accuracy of modelled ligand binding pocket.

Homology Modelling Using Multiple Templates

The structure for integrin $\alpha\beta6$ was predicted through homology modelling by using multiple templates (Sowmya *et al.*, 2014). The specific interaction of integrin $\alpha\beta6$ and uPAR is known to be associated with cancer progression and was studied using the predicted structure. The crystal structure of the extracellular domains was subsequently determined (PDB ID: 4UM9) and the RMSD between the predicted and experimental structures is $<1 \text{ \AA}$, demonstrating the accuracy of the predicted model.

Ab initio Modelling

The structure of CT296 protein was predicted by *ab initio* modelling through the I-TASSER server (Kemege *et al.*, 2011). CT296 is present in *Chlamydia trachomatis*, which is a bacterial pathogen responsible for non-heritable blindness. It was previously suggested that CT296 shows similarity to the ferric uptake regulator and has DNA binding motifs. The predicted model was not consistent with this information. The XRC of CT296 was then determined at a resolution of $1.8 \text{ \AA}$, supporting CT296 not having functional similarity to the ferric uptake regulator and also having DNA binding sites. When compared, the predicted model had significant similarity to the XRC (RMSD: $2.72 \text{ \AA}$).

Threading-Based Homology Modelling

The β_1 -adrenergic receptor (β_1 -AR) belongs to GPCR superfamily and is known to play an important role in cardiovascular function and disease, serving as a drug target for the management of cardiovascular diseases. Through threading-based homology modelling approach, a 3D model for β_1 -AR was constructed that was further utilized in docking four agonists (Carmoterol, Dobutamine, Isoprenaline and Salbutamol) to study the binding modes of β_1 -AR (Ul-Haq *et al.*, 2015). The human β_1 -AR structural model assisted the authors to understand its binding mechanism, for future targeted structure-based drug molecule development.

Let's Start to Model:

Given the poor representation of membrane proteins in the PDB and the complications involved in building a model for protein with multiple transmembrane segments, the example chosen to illustrate the steps involved in building a 3D model of a protein is that of a membrane protein.

Case Study

GPCRs represent the largest family of membrane proteins and are targets for almost half of the drugs (Tautermann, 2014). There are a total 130,314 GPCR protein sequences from multiple organisms, including *Homo sapiens*, available in UniProt (as on August 2017), but only 436 crystal structures of GPCRs are present in GPCRdb, which includes 44 unique crystallized receptors and 43 unique ligand-receptor complexes, indicating a large sequence structure gap. GPCRs consist of seven transmembrane (Schmiedeberg *et al.*, 2007) helices that are connected through three extracellular loops (ECLs) and three intracellular loops (ICLs) with extracellular N-terminus and intracellular C-terminus (Clark, 2017). Short wave sensitive opsin is one of the GPCR whose structure is predicted through homology modelling, with consideration of motifs and patterns, and in this case study is used as an example.

Obtaining Target Sequence

Download the amino acid sequence of the target, i.e., short wave sensitive opsin (OPSB_BOVIN) in FASTA Format from UniProt (UniProt ID: P51490, see Relevant Website section).

Sequence

- Use TMSEG (Bernhofer *et al.*, 2016) to predict transmembrane regions of OPSB_BOVIN. Enter query sequence in FASTA format and select transmembrane helices option.

- b. Use Predictprotein (see Relevant Websites section) to confirm transmembrane regions and to predict secondary structure of non-membrane segments.
- c. Motifs and patterns can be predicted by number of available webserver and their knowledge can also be gained from available literature. Each TM of GPCR contains at least one motif that can be very helpful for generating optimal alignment (Van Der Kant and Vriend, 2014). Table 7 shows the motifs retrieved from the literature. Patterns/motifs predicted from different webserver are shown in Table 8 (only strong matches are shown).
- d. Extracellular part of GPCRs are involved in ligand recognition and binding. The ligand binding pockets are extremely diverse among GPCR members in terms of shape and features for recognition of varied ligands (Katritch *et al.*, 2012). Despite the diverse ligands, residues 3.32, 3.33, 3.36, 6.48, 6.51 and 7.39 (numbered according to Ballesteros–Weinstein numbering (Ballesteros and Weinstein, 1995)) are known to make consensus interactions with ligands among class A GPCRs. Residues from other transmembrane regions tend to interact with specific ligands to a varied extent. Therefore, TM3, TM6 and TM7 serve as a consensus cradle for the ligand binding pocket. Alteration of residues in these specific topological positions leads to ligand specificity in different receptors (Venkatakrishnan *et al.*, 2013). OPSB_BOVIN sequence is represented in Fig. 2 with predicted TM regions, motifs, consensus ligand binding pocket and cysteine residues involved in the formation of disulphide bridges.

Table 7 Motifs of GPCR sequences retrieved from the literature

TM	Motif
ECL2	Disulphide bridge between TM3 (Cys ^{3.25}) (Ballesteros and Weinstein, 1995) and ECL2 (Venkatakrishnan <i>et al.</i> , 2013)
1	GXXXN (de March <i>et al.</i> , 2015)
2	NLXXD (Miguel <i>et al.</i> , 2017)
3	DRY (Deupi <i>et al.</i> , 2007) SX ₃ LX ₂ IX ₂ D(E,H)RY (Costanzi, 2012)
4	WX _{8,9} P (Costanzi, 2012)
5	FX ₂ PX ₇ Y (Costanzi, 2012)
6	CWXP (Miguel <i>et al.</i> , 2017) FX ₂ CW(Y,F)XP (Costanzi, 2012)
7	NPXXY (Sato, 2016)

**Fig. 2** OPSB_BOVIN sequence features. Predicted TM regions (highlighted in yellow), motifs (bold text) and patterns (underlined), cysteine residues involved in disulphide bridge formation (green) and consensus ligand binding cradle of class A GPCRs (red) are shown.

Template Identification and Selection

- Run BLAST against Protein databank to retrieve the potential templates. OPSB_BOVIN has 44% sequence identity and 92% query coverage with bovine rhodopsin (PDB ID: 3OAX) according to BLAST results. Due to high sequence identity, query coverage and completeness of structure, 3OAX can be selected as a template, but there is another structure of bovine rhodopsin deposited in PDB (PDB ID: 1U19) with a resolution of 2.2 Å while 3OAX has a resolution of 2.6 Å. Due to the better resolution than 3OAX, 1U19 is selected as template for modelling OPSB_BOVIN.
- Download the PDB file of 1U19 from Protein databank (see Relevant Websites section).

Target Template Alignment

- Before alignment, the PDB file must be edited, if needed. For example, if the template has multiple chains and one of the chains is selected to serve as a template, then the rest of the chains must be deleted by use of the PDB visualizer such as UCSF Chimera. The PDB file 1U19 has two chains A and B, since we only need chain A, chain B is deleted by selecting the chain B in UCSF Chimera and then deleting it. If the PDB file contains any protein that is co-crystallized with the template protein, then it must also be removed. Additionally, all non-standard residues must be removed except the ligands (if required) and metals ions as they are important for folding specially for small proteins. Non-standard residues are present in the form of HETATM record in the PDB file and can be deleted using any text editor. There is one modified residue (HETATM) in the PDB file of 1U19 (line number 871–873), labelled as X in the sequence, it should also be removed. There might be some missing residues in the template, so the structure derived sequence of the template will be used which can be retrieved by clicking sequence in the tools tab in UCSF Chimera and saving it into a separate file. The gaps will be inserted in place of missing residues before alignment. There are no missing residues in 1U19.
- The MSA webserver, T-COFFEE, is used to align OPSB_BOVIN and 1U19. The membrane protein option is selected before submitting the sequence.
- Knowledge of motifs, patterns and ligand binding cradle gained during sequence analysis step can now be used to optimize the alignment between query and template. Motifs in OPSB_BOVIN are well aligned to 1U19. Due to the high sequence identity, there are no insertions and deletions in the predicted transmembrane regions. The only gaps present in alignment are within the N- and C-termini, which can be ignored, as these regions are usually not conserved in membrane proteins. According to the alignment between 1U19 and OPSB_BOVIN (Fig. 3), the last five residues of OPSB_BOVIN do not have a corresponding residue from the template, and thus these residues will not be modelled due to lack of matching template residues. These residues can be removed from alignment before model building.

Model Building, the Manual Way

Build the model of OPSB_BOVIN using Modeller, by following the tutorial provided (see Relevant Website section). It is better to build multiple models (say 5) and then select the final model on the basis of the lowest objective function (Fig. 4).

Fig. 3 Alignment of Bovine rhodopsin (1U19: A) and OPSB_BOVIN sequence given as an input to Modeller. TM regions of 1U19 and predicted TM regions of OPSB_BOVIN are highlighted in yellow with disulphide bridge forming cysteine residues (green), motifs of both sequences (bold text), patterns (underlined), ligand binding cradle of OPSB_BOVIN (red), ligand binding pocket of 1U19 (blue) and residues without a template are highlighted in red. Disulphide bridge is indicated by a dashed line.

Fig. 4 OPSB_BOVIN model, from manual model building.

Structure Validation

- Use PSVS server to validate the structure. PROCHECK program present in PSVS server reports the conformationally allowed regions of the residues. High quality X-ray structures have at least 85% of the residues in conformationally allowed regions (Sowmya *et al.*, 2014). For the predicted model, 99.7% of the residues are in conformationally allowed regions as reported by PROCHECK, including 88.3% of which are favorable and 11.4% are in allowed regions. RMSD for bond lengths and bond angles is 0.019 Å and 2.1° respectively, which should be lower than 0.02 Å and 4° for a good quality structure.
- Closeness of the template and query determines the accuracy of the predicted structure, which is often measured by either Root Mean Square Deviation (RMSD) or global distance test (GDT_TS). The greater the similarity between the template and the query, the higher is the resolution. Sequence similarity over 50% and $\text{RMSD} \leq 1$ Å corresponds to high resolution structure. If similarity is between 30% and 50% and $\text{RMSD} \leq 1.5$ Å the resolution is medium (Carlsen and Røgen, 2015). The RMSD between the OPSB_BOVIN and 1U19 is 0.267 Å. RMSD can be retrieved by superimposing the predicted structure and template structure in UCSF Chimera (PDB visualizer).
- Use the Molprobiy server to look for favored and poor rotamers which are the low energy conformations of side-chain dihedral angles. The correct assignment of rotamers to each amino acid is essential for a thermodynamically stable structure (Bhuyan and Gao, 2011). The quality of predicted side chain can be analyzed by identifying the favored rotamers in the 3D structure of a protein (Harder *et al.*, 2010).
- Use the ProTSAV server that gives a normalized average *Z-score* based on ten diversified structure validation programs. A *Z-score* closer to 0 represents a good quality structure. The manual model for OPSB_BOVIN has a *Z-score* of 0.5846 (Table 9).
- Literature: It is observed that TM3 and ECL2 are connected together by a disulphide bridge (Fig. 5), which is the characteristic of majority of class A GPCRs (Venkatakrishnan *et al.*, 2013).

Automated Structure Prediction

Plenty of online servers are available that take a target sequence as an input and pass it to a pipeline of various programs to predict the 3D structure of the target protein. Almost all such webserver have a user-friendly interface. It is important that one should select the server carefully to have a good model. Top ranked servers (according to CASP ranking) were used in this case study to predict the model of OPSB_BOVIN, namely I-TASSER, RaptorX, and InfFOLD, among others. It should be noted that in this case, we allowed the servers to select the best template(s). The comparisons of structure validation results for predicted structures according to the steps in Section Structure Validation by use of the automated servers and the manual modelling is shown in Table 9.

Table 9 Comparison of structure validation results of manual modelling and automated modelling

Description		Manual model	RaptorX	IntFOLD	I-TASSER
Ramachandran plot (PSVS)	Favored (%)	88.3	92.5	85.4	82.5
	Allowed (%)	11.4	6.9	13.0	17.5
	Outliers (%)	0.3	0.6	1.6	0.0
RMSD for bond lengths (Å) (PSVS)		0.019	0.020	0.019	0.014
RMSD for bond angles (PSVS)		2.2°	3.0°	2.2°	2.3°
Favored rotamers (%) (Molprobit)		91.06	87.75	87.75	78.15
ProTSAV score (ProTSAV)		0.5846	0.5907	0.6042	0.5593
RMSD (Å)		0.260	1.605	0.203	1.177
Template(s) used		1U19 (Bovine Rhodopsin)	4ZWJ (Human rhodopsin)	2G87 (Bathorhodopsin)	Multiple ^a

^a4ZWJ (Human Rhodopsin); 1GZM (Bovine Rhodopsin); 1U19 (Bovine Rhodopsin); 2KS9 (Substance P receptor); 2G87 (Bathorhodopsin).

**Fig. 5** Disulphide bridge between ECL2 and TM3.

For all the predicted models by the automated servers and the manual modelling, more than 90% of the residues were in the allowed regions according to PROCHECK embedded in PSVS server. The RMSD for bond lengths and bond angles from native structures for all the models were good but there were not enough favored rotamers, which should be more than 98%, suggesting that the side chains need refinement. In the manually predicted model, the favored rotamers were comparatively better than the automated models.

N- and C-Termini

The automated RaptorX server predicted long N- and C-termini as compared to the other predictions, it is because of the long indels present in the alignment of both termini between the OPSB_BOVIN and the template 4ZWJ selected by the server. Only few residues in N-terminus are modelled on the basis of template (4ZWJ) as seen in the alignment (Fig. 6).

Helical Bundle

According to both the manual and automated models, the predicted TM1, TM2 and TM4 are modelled in the same manner and have the same positions in each predicted model. There are slight differences in the start and end positions of TM3 between the manually predicted model and the I-TASSER model. There was a variation in the prediction of TM5, where I-TASSER and RaptorX had predicted a long TM5 as compared to the manual and IntFOLD server predictions. This is because the template (4ZWJ) chosen by the automated servers had a long TM5 (Fig. 6). The start and the end of TM6 was the same across all the predictions, except for I-TASSER which had only

Fig. 6 Alignment of OPSB_BOVIN with 4ZWJ used by RaptorX to generate the 3D model of OPSB_BOVIN. N-terminus, C-terminus and TM5 of both OPSB_BOVIN and 4ZWJ are highlighted in yellow.

Fig. 7 Snake plot for 1U19, showing motifs/patterns (yellow), cysteine residues involved in disulphide bonding (green) and residues in ligand binding site (blue).

one residue difference. The start position of TM7 was the same for all the predictions, but there was a disagreement in the end position. TM boundaries of each predicted model can be seen clearly through snake plots in Figs. 7–9. Snake plots for 1U19 and OPSB_BOVIN are downloaded from GPCRdb (Munk *et al.*, 2016) and edited according to the predicted models.

Intracellular Loops

The structure of the predicted intracellular loop was nearly similar in all the models, except intracellular loop 3 (ICL3 in Fig. 9) of models predicted by RaptorX and I-TASSER, where in these models the TM5 was longer, and thus the ICL3 was shorter, compared to the other two predicted models (Fig. 10).

Fig. 8 Snake plot for manual model, showing motifs/patterns (yellow), cysteine residues involved in disulphide bonding (green) and residues in ligand binding site (red).

Disulphide Bridges

All of the predicted models had a single disulphide bridge between cysteine residues at positions 108 and 185. Thus, all models were consistent in building a viable disulphide bridge between the correct cysteine residues.

Secondary Structure Elements

All predicted models contained 7TM helices. Two β -strands were present in ECL2 of all the predicted models. According to the I-TASSER prediction, two more β -strands were present in the N-terminus. One small helix was present in ECL2 in a model predicted by RaptorX.

Automated Versus Manual Modelling

Automated modelling is convenient when high sequence identity exists between the query and the template, but for low sequence identity cases, manual modelling is preferable for the following reasons:

- Alignment editing is required in most of the cases. For instance, in a model predicted by RaptorX, the C-terminus and N-terminus can be improved by adjusting the gaps in alignment. Many automated servers do not allow alignment editing.
- A careful study of template is required for its selection (Section Template Selection). We can see from the case study that the manual *versus* automated selection of the template affected the model; for example, resulting difference in the length of predicted TM5 by RaptorX and I-TASSER automated servers due to the different templates. Most of the automated servers focus on sequence identity between the target and template for selection; only some incorporate additional features, such as secondary structure and solvent accessibility, among others. Some automated servers do allow the user to specify the templates, but this might be risky as it can often result in a bad model if the template selection criteria are not well applied (Fasnacht *et al.*, 2014).
- Many servers do not allow use of multiple templates.
- Servers normally take one to several days for predicting the structure depending upon the load on the server, but through manual prediction, models can be built quickly as compared to automated servers.

Despite the above facts, automated servers do provide models that can give clues about the structure of a protein and in many instances, can serve as a first guess, before careful manual model building.

Conclusion

Enormous advancement has been witnessed in the area of protein structure prediction methods over the past decade. The nor-epinephrine transporter (NET), a drug target for various mood related and behavioral disorders, such as depression, is a notable success story in the application of such prediction methods. There was not a single good resolution atomic structure available for NET.

Fig. 9 Snake plots for RaptorX (A), IntFold (B) and I-TASSER (C) models, showing motifs/patterns (yellow), cysteine residues involved in disulphide bonding (green) and residues in ligand binding site (red).

Computational model of NET was constructed by use of the X-ray structure of leucine transporter LeuT from *Aquifex aeolicus* as a template. The built model was then used for virtual ligand screening against the binding site, which resulted in the identification of 10 already tested NET inhibitors and five novel ligands. Predicted ligands were then validated experimentally to be the potential inhibitors of NET (Schlessinger *et al.*, 2011). Despite the continuous progress in this field, there are cases where the proteins can be difficult to model. For example, *HpUreI*, a proton gated urea channel from *Helicobacter pylori* known to be involved in gastric infection, was one of the targets for CASP round 10. The X-ray structure of *HpUreI* showed a novel fold which was not predicted with accuracy by any of the template based modelling approach; and was predicted with little accuracy by the template free approach I-TASSER, but less than one third of the residues were in proximity to the corresponding X-ray structure (Kryshtafovych *et al.*, 2014). With continuous improvement in protein structure prediction methods, these challenges are hoped to be addressed. For example, numerous methods are now available for modelling membrane proteins; RosettaMP (Alford *et al.*, 2015) is one such method.

Fig. 10 Superimposition of model structures from IntFOLD (blue), I-TASSER (brown), RaptorX (green) and manual mode (pink).

Biographical Sketch

Amara Jabeen is a PhD student in the Department of Chemistry and Biomolecular sciences at Macquarie University. She is working on functional annotation of odorant receptors using bioinformatics approaches. She is predicting the structures of olfactory receptors through computational methods. She has worked on genome wide analysis of T6SS proteins in *Acidovorax avenae* subsp. *avenae*, *Acidovorax avenae* subsp. *citruilli* AACOO1 and *Acidovorax avenae* subsp. *avenae* ATCC19860 through bioinformatics approaches. She has also worked on structure prediction of Lipase H and bioinformatics analysis of Lipase H and Extracellular matrix protein 1 (ECM1).

Abidali Mohamedali is Lecturer at Macquarie University in the Faculty of Science and Engineering. He completed his PhD in 2010 studying, using proteomics, the effects of single mutations in mouse model on brain development in the autism spectrum disorder, Rett syndrome. He then returned to Macquarie University undertaking a post-doc to study the biology of metastasis in colorectal cancer using proteomics and to determine novel therapeutic targets and develop novel technologies to examine the plasma proteome.

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, United States, Singapore and Australia, as well as a consultancy in industry. Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books, as well as contributed several articles to Springer's Encyclopedia of Systems Biology. She is currently the Editor-in-Chief of Elsevier's Encyclopedia of Bioinformatics and Computational Biology, as well as the Bioinformatics Section Editor for Elsevier's Reference Module in Life Sciences.

Structure-Based Drug Design Workflow

Introduction

Drug discovery in pharmaceutical companies was dominated by the process of generating synthetic compounds through combinatorial chemistry where many trials and errors occur, with a hope obtaining new active compounds (Li, 2013). It was a long way with a lot of efforts which spends time, money, and labor. For an illustration, pharmaceutical companies typically required 10–15 years with expenditure around US\$800 to US\$1.8 billion to release a drug to the market (Macalino *et al.*, 2015). With advances in high-throughput crystallography, computer hardware, and molecular modeling software, a new approach was introduced in the drug development by employing the three-dimensional (3D) structure of the biological target to design active molecules rationally. This method is called structure-based drug design (SBDD). SBDD started to flourish after the discovery of an HIV protease inhibitor (saquinavir) which exploited the 3D structure of the target macromolecule in its rational design (Li, 2013). Since then, SBDD has become an established tool which accelerates the process of drug development. Nowadays, SBDD is an integral part of the drug discovery and development in many modern pharmaceutical companies (Macalino *et al.*, 2015; Muegge *et al.*, 2017). Fig. 1 summarizes the workflow for SBDD which includes target selection, target structure evaluation, binding site identification, molecular docking and scoring, and lead compound optimization to generate new drug.

Steps Involved in the Process of SBDD

Drug Target Selection

Selection of drug targets is the first step in SBDD. It is an essential part because SBDD relies on the 3D of target macromolecules in the process of drug design. Drug targets can be enzymes, receptors, ion channels, transport proteins, DNA/RNA and the ribosome, or targets of monoclonal antibodies (Imming *et al.*, 2006). Drug targets are identified and validated through direct biochemical approaches, genetic interaction, computational inference techniques or combination of these methods. These methods are comprehensively reviewed by Schenone (Schenone *et al.*, 2013). A thorough literature survey can assists in the selection of drug targets associated with the small molecules of interest.

Fig. 1 Workflow of structure-based drug design (SBDD).

Evaluation of Drug Target Structures

Once the drug target has been identified, the next step is obtaining its 3D-structure from the Protein Data Bank (PDB; see “Relevant Websites section”) or Cambridge Crystallographic Data Center (see “Relevant Websites section”). Experimental methods for determining the drug target structures are X-ray crystallography, nuclear magnetic resonance (NMR), and cryo-electron microscopy (EM) approaches. Crystal structures are the widely used source of structural information for drug design (Anderson, 2003; Petsko and Ringe, 2010). The quality of crystal structures is usually assessed from their resolutions, R factors, coordinate errors, temperature factors, and chemical correctness (Anderson, 2003). These parameters are usually reported in the ‘REMARK’ part of the PDB file. Crystal structure with resolution up to 2.5 Å is acceptable for drug design. The R factor and R_{free} , which reflect the correlation between the model and experiment, should be below 25 and 28%, respectively. The coordinate error must be between 0.2 and 0.3 Å. Temperature factors of atoms, which indicate an atomic position error, are less than the average temperature factor for the molecule. Stereochemical deviations of bond angles and lengths are less than 3° and 0.015 Å, respectively, whereas planar atoms should be less than 0.015 Å out of the plane. Ramachandran plot is then used to assess the chemical correctness of backbone ϕ and ψ angles where the percentage of at least 90% in the most favored regions are preferred (Laskowski *et al.*, 2001).

However, if experimental structures are unavailable, comparative modeling, threading, or *ab initio* protein modeling is used to generate 3D-models for drug targets. The same evaluation parameters are applied to the generated models. A great number of programs are available for protein structure validation, for instance, PROCHECK (Laskowski *et al.*, 2001) and WHATIF (Rodriguez *et al.*, 1998).

Binding Site Identification

The binding site is usually a hollow part or pocket of the drug target where the small molecule or ligand binds (Macalino *et al.*, 2015). The features of the binding site that are important for ligand binding include potential H-bond donors and acceptors, unique hydrophobic surfaces and molecular surface size (Anderson, 2003; Macalino *et al.*, 2015). The knowledge of ligand binding site and its features are essential in SBDD and can be extracted from experimental structures and mutation studies. However, the information of ligand binding site may be unavailable. Fortunately, *in silico* approaches are there that can be used to predict potential binding sites. These approaches are implemented in many programs or online servers. A list of binding site prediction servers and programs are summarized in Table 1.

Molecular Docking

Once the drug target and its binding site are identified, structures of small molecules (ligands) are modified *in silico*. The modified ligands are usually subjected to molecular docking to predict binding modes and affinities of ligands (Forli *et al.*, 2016). Molecular docking methodologies (listed in Table 2) consist of searching algorithms and scoring functions. These searching algorithms explore possible conformations of small molecules while interacting with residues in the binding site. The scoring functions then rank the possible conformations and are crucial for SBDD. The scoring functions are classified into force field-based, empirical-based, and knowledge-based functions (Macalino *et al.*, 2015). Force field-based functions use physical atomic contacts in the target-ligand complex to compute binding affinity, where solvation and entropy terms can be evaluated. In empirical-based functions, the calculation is performed by fitting fewer energy terms, such hydrophobic and electrostatic interactions, to experimental binding affinity data. Knowledge-based functions employ a statistical method to derive binding energy from a training set of protein-ligand.

Table 1 Popular servers and programs for binding site prediction

Program/ server	Availability	Prediction method	URL
Cavicator	Free as standalone program	Analysis of grid-based geometric (Gao and Skolnick, 2013)	http://cssb.biology.gatech.edu/Cavicator

Lead Compound Optimization

The lead compound suggested by molecular docking is then subjected to a cycle of optimization. The compound must be synthesized and assessed by both *in vivo* and *in vitro* experiments. After these experiments conducted, the step returns to the computational stages. Another analog can be developed and estimated for their binding affinity through molecular docking. Since molecular docking roughly estimates the binding affinity of binding for ligands to the target macromolecule, another sophisticated approach like molecular dynamics or free energy perturbation may be required to obtain more realistic conformations of new analogs or binding affinity predictions (Forli *et al.*, 2016). Subsequently, the analogs are synthesized in the laboratory and assayed for their binding affinities. These computational and experiment are iteratively performed until the desired binding affinity of the ligand is reached (Macalino *et al.*, 2015).

At the final step of lead compound optimization, analyses of absorption, distribution, metabolism, excretion, and toxicity (ADMET) are highly required (Macalino *et al.*, 2015). After being administered to the body, drugs may need to absorb properly by crossing various barriers like a gastrointestinal tract to enter the bloodstream. Through bloodstream, drugs are then distributed to their effector sites in muscles or organs where they are metabolized and then excreted. Few of the drug metabolisms may result in toxic compounds which can be hazardous. There are many web servers and programs available for predicting ADMET, for instance, QikProp, SwissADME, and ADMET Predictor. Thus, ADMET estimation can be optionally performed before synthesis step for prioritizing compounds suggested by molecular docking (Table 3).

Practical Applications of SBDD in Pharmaceutical Industry

HIV Anti-Viral Drug

SBDD has engendered the pharmaceutical industry with many successes for instance drugs for HIV, influenza, and cancer. The discovery of an antiviral drug for HIV was the leading example and the milestone for the establishment of SBDD. Advancements in crystallography technique lead to the determination of structure for HIV protease in the late 1980s. Saquinavir, the first anti-HIV drug was developed using the crystal structure of the protease. Since then the further development assisted by SBDD have yielded nine FDA-approved anti-HIV drugs the latest one is darunavir (Li, 2013).

Influenza Anti-Viral Drug

SBDD has also contributed to the discovery of influenza antiviral drugs. By using the crystal structure of neuraminidase (NA), zanamivir was designed from 2-deoxy-2,3-didehydro-N-acetylneuraminic acid (DANA) as the lead compound. The knowledge

Fig. 2 Structures of balanol and its fluorinated analogs. The balanol structure has been divided into three moieties that correspond to different subsites based on its structural overlay with ATP.

extracted from the crystal structures of NA in complex with DANA and zanamivir also helped in the design of oseltamivir which has a more improved bioavailability than zanamivir. After the discovery of oseltamivir (OTV), the overlaid crystal structure of a furanose isomer with DANA in complex with N9 subtype revealed that the four functional groups (side chains) in both complexes had similar orientation and interactions in the binding site. Therefore, it was concluded that the central ring is not an absolute factor in the development of potential NA inhibitors. Instead, it is the relative position of the functional groups in the active site which is important (Babu *et al.*, 2000). For this reason, cyclopentane-based compounds (different central ring from the previous compounds) were developed and as a result peramivir was discovered. In 2006, FDA approved the usage of peramivir in the injectable formulation (Itzstein and Thomson, 2009).

Case Study

To illustrate SBDD, protein kinase C ϵ (PKC ϵ) is employed as an example. Unlike other PKC isoforms that possess ambiguous roles in cancer development, PKC ϵ shows clear oncogenic activities and is implicated in invasion and metastasis of cancer cells, such as human breast, glioma, and renal carcinoma (Garg *et al.*, 2014). A fungal natural product, called balanol, was discovered to competitively inhibit PKC ϵ targeting its ATP site (Kulanthaivel *et al.*, 1993). However, the compound also unselectively inhibits other PKC isoforms. Interestingly, a stereospecific fluorination on balanol yielded an analog (hereafter mentioned as ligand 1) with enhanced activity and selectivity to PKC ϵ (Patel *et al.*, 2017).

The structure of balanol is an ATP mimic and divided into benzamide (ring A), azepane (ring B), and benzophenone (ring C and D) moieties. It completely occupies the ATP binding site (Taylor *et al.*, 2004). In particular, the benzamide moiety replaces the adenine subsite, whereas the azepane and the benzophenone moieties fill the ribose and the triphosphate subsites, respectively (Fig. 2).

Here, SBDD is utilized to design another new analog of balanol with improved binding activity to PKC ϵ . Since the experimental structure of PKC ϵ is unavailable, its 3D model was generated using homology modeling. To build the model, two crystal structures, a mouse protein kinase A (PDB ID 1BX6) and a human PKC θ (3TXO), were used as templates. The details about homology modeling method are presented in another article of this book.

The following part is dedicated to demonstrate how SBDD, using a molecular docking approach assists in predicting binding affinity of ligand 1 and another analog of fluorinated balanol (ligand 2). A widely used program AutoDock (Forli *et al.*, 2016) is used in this case study. Autodock is freely available and can be downloaded from “see Relevant Websites section”. Discovery Studio Visualizer and AutoDockTools are utilized in the molecular docking preparation and analysis. Discovery Studio Visualizer is freely distributed at “see Relevant Websites section”, whereas AutoDockTools (ADT) which is part of MGLTools can be downloaded from “see Relevant Websites section”. Coordinate files of the ligands and PKC ϵ are provided as SBDD.zip.

Ligand Preparation

1. Create the coordinate files for ligands. The coordinates for the two ligands used in this case study were generated using homology modeling, which included a ligand mapping from the template 1BX6 to the resulting homology model of PKC ϵ . The balanol structure was modified in Discovery Studio Visualizer to yield two fluorinated balanol analogs as ligands for PKC ϵ . The first ligand is balanol with a fluorine atom on the position of C(5S) which is provided as ligand_1.pdb. It was prepared by the following steps (Fig. 3): open the balanol structure (bal.pdb) in Discovery Studio Visualizer program, select C5, on the menu bar choose ‘Chemistry $\rightarrow$ Hydrogens $\rightarrow$ Add’, then select the hydrogen atom on the position of C(5S), on the menu bar select ‘Chemistry $\rightarrow$ Element $\rightarrow$ F’ (Fig. 3). Ligand 2 is the further modification of the first ligand with an additional hydroxymethyl on the benzamide moiety. The coordinate file of this ligand is provided as ligand_2.pdb. Both ligands have negative charges on

Fig. 3 Steps in incorporating the fluorine substituent to the azepane ring of balanol. Fluorine was added to the position C5(S).

the phenolic C6''OH and carboxylic C15''O₂H and a positive charge on the secondary amine N1 as suggested by our previous investigation (Hardianto *et al.*, 2017).

2. Load the coordinate file of the first ligand (ligand_1.pdb) to ADT. On ADT menu, choose 'Ligand → Input → Open' and select 'PDB files' for the file type, then browse to the folder where ligand_1.pdb is located, select the file and click 'Open'. ADT will add charges if required, merge nonpolar hydrogens, and assign suitable atom types. The ligand will appear in the viewer window. Click 'OK' on the popup window.
3. Prepare the PDBQT file for the first ligand (ligand_1.pdb). To do this, select 'Ligand → Torsion Tree → Detect Root' which will identify the center of the torsion tree. For this study case, we use the default torsional degrees of freedom. However, if a customization of such degree of freedom is needed, select 'Ligand → Torsion Tree → Choose Torsions'. Rotatable bonds are denoted in green and rigid ones are in the red, whereas non-rotatable bonds that are potentially rotatable are in magenta. Click the bonds to change the rotation flexibility. Click 'Done' to complete this step. Select 'Ligand → Output → Save as PDBQT', and then choose 'Save' to write the file ligand_1.pdbqt.

Receptor Preparation

Prepare the coordinate file of the receptor, i.e., PKCε. The coordinate file for receptor was generated using a homology modeling approach and is provided as PKCepsilon.pdb. Open the file by clicking 'Grid → Macromolecule → Open', and choose 'PDB files (.pdb)' for the file type. Click on file PKCepsilon.pdb and click 'Open'. A popup window will appear, click 'Save' to write the file PKCepsilon.pdbqt (Fig. 4).

Grid Maps Preparation and Generation

1. Prepare a grid parameter for generating the atomic affinity maps. Select 'Grid → Macromolecule → Choose' and choose 'PKCepsilon' in the popup window. Select 'Grid → Set Map Types → Choose Ligand' and choose 'bal_1c'. Set the grid box of the search space by selecting 'Grid → Grid Box', which prompts a window for defining the center and size of the box. Choose 'Center → Center on Ligand' to define a minimal box. To adjust the size and center of the box, drag left the thumbwheels to decrease or right to increase the value. Choose 'File → Close Saving Current'. Select 'Output → Save GPF' to save the grid parameter file as 'ligand_1.gpf'.
2. Run AutoGrid from the command line. Open a terminal window and go to the directory where the coordinate files and grid parameter file (ligand_1.gpf) are located. Make sure executable file of AutoGrid (autogrid4) is in the same directory. Type the following command:

```
autogrid4.exe -p ligand_1.gpf -l ligand_1.glg
```

Molecular Docking

1. Create a docking parameter file. Select the receptor PDBQT file by clicking 'Docking → Macromolecule → Set Rigid Filename' and choose 'PKCepsilon.pdbqt' in the directory where it is located. For the ligand, click 'Docking → Ligand → Choose' and

Fig. 4 Display of AutoDockTools.

select 'ligand_1', and accept the default ligand docking parameters. To set searching parameters, click 'Docking → Search Parameters → Genetic Algorithm Parameters', change 'Number of GA Runs' to 50, and accept the rest default parameters. Then click 'Docking → Docking Parameters' and use default parameters. Select 'Docking → Output → Lamarckian GA' to write the docking parameter file as 'ligand_1.dpf'.

- Run AutoDock from the command line. In a terminal window, go to the directory containing the coordinate files and docking parameter (ligand_1.dpf). By assuming AutoDock (autodock4.exe) is in the same directory with the coordinate files and docking parameter, type the following command
`autodock4.exe -p ligand_1.dpf -l ligand_1.dlg`

Analysis

- Visualize the molecular docking results. Load the results by selecting 'Analyze → Dockings → Open' and choose the ligand_1.dlg file. Select 'Analyze → Conformations → Play Ranked By Energy' to visualize the docking result. Click '&'-like button to open 'Set Play Options' panel, then check 'Show info' to display 'conformation info' dialog box which contains predicted binding energy and its components. When displaying the conformation 1, on the Set Play Options dialog box, click 'Build Current' and save the conformation of docked ligand 1 as conf1_ligand_1.pdbqt in your current working directory.
- Visualize docking pose cluster based on binding energy values. To do this, select 'Analyze → Clustering → Show'.
- Visualize ligand-protein interaction in Discovery Studio Visualizer. On Discovery Studio Visualizer, click 'File → Open' and select conf1_ligand_1.pdbqt in your working directory. On the left side of Discovery Studio Visualizer window, click 'View Interactions' and then 'Ligand interactions'.

Fig. 5 Binding-energy-based clustering of docking poses of ligands (A) **1** and (B) **2** in the ATP site of PKC ϵ .

For ligand **2**, steps in sections “Ligand Preparation” to “Molecular Docking” are applied to predict the binding affinity of this balanol analog, except Section “Ligand Preparation” step 1.

Discussion

Ligand **1** has an experimental binding affinity of 0.40 nM to PKC ϵ . Molecular docking using AutoDock suggests 15 pose clusters based on predicted binding energy for this ligand when it is bound to the ATP site of PKC ϵ . Binding energy values of the clusters span between -7.0 and -15 kcal/mol. The main cluster contains 21 poses with predicted binding energy values near -15 kcal/mol (**Fig. 5(A)**), which are the most negative among the others. In this cluster, the strongest docking pose has a binding energy of -14.74 kcal/mol. According to AutoDock result, the docking pose shows an intermolecular energy of -18.02 kcal/mol, a van der Waals and hydrogen bond (H-bond) desolvation energy of -15.90 kcal/mol, electrostatic energy of -2.12 kcal/mol, total internal energy of -1.96 kcal/mol, torsional energy of 3.28 kcal/mol, and unbound energy of -1.96 kcal/mol.

Visual inspection of this docking pose in the ATP site of PKC ϵ suggests that the hydroxyl group on the benzamide moiety (C5'OH) interacts via two H-bonds with Glu489 and Val491 in the adenine subsite (**Fig. 6(A)**). The benzamide moiety may interact more tightly by introducing an additional hydroxyl group adjacent to C5'OH. The presence of such additional hydrogen group may strengthen the binding of balanol analog to PKC ϵ . However, introducing such hydroxyl group may be problematic, since the presence of two adjacent hydroxyl groups in the benzamide moiety may lead to the unstable compound. Thus the additional hydroxyl group is incorporated as a hydroxymethyl substituent on the benzamide moiety to form the second ligand. The coordinate file of the second ligand is provided as ligand_2.pdb.

Molecular docking of the second ligand to PKC ϵ predicted that the incorporation of the hydroxymethyl group results in an improved binding affinity to this protein kinase. Binding-energy-based grouping in ADT categorizes the resulting docking poses into seven clusters (**Fig. 5(B)**). The major cluster contains 37 docking poses with predicted binding energy values negative than -15 kcal/mol, which shows stronger interaction than the ligand **1**. Binding energy components of the second ligand are stronger than those of the first ligand such as intermolecular and desolvation energy which is -18.02 and -15.90 kcal/mol, respectively. Furthermore, visual assessment using Discovery Studio Visualizer shows that the presence of an additional hydroxyl group, as a hydroxymethyl substituent, enhances the H-bond interactions between the benzamide moiety and the ATP site of PKC ϵ (**Fig. 6(B)**). This increased interaction resulted in greater binding affinity of the second ligand to PKC ϵ .

Future Directions

In SBDD, molecular docking is a relatively fast and computationally cheap method in the rational drug design process to predict binding modes and affinities of small molecules to the drug targets of interest. However, with the continuous improvement of hardware, other approaches that were previously considered as computationally expensive and demanding are becoming feasible and cheaper. For instance, molecular dynamics simulation (MD), which is supported by the advance development of graphical processing unit (GPU) cards, is now more affordable (*Le Grand et al., 2013*). Thus, MD can more be routinely applied in SBDD. MD can accommodate protein flexibility and solvation effects, which normally cause problems in scoring and ranking of small molecules while using docking approach (*Macalino et al., 2015*). Additionally, the development of the accelerated MD versions alleviates the energy barrier issue in conventional one (*Miao et al., 2015*).

Fig. 6 H-bond interactions made by ligands (A) **1** and (B) **2** with residues of Glu489 and Val491 in the ATP site of PKC ϵ . H-bonds are indicated by green dashed lines.

Another approach in computer-aided drug design is ligand-based drug design (LBDD) which utilizes a set of small molecules with a particular activity and does not need the prior knowledge of the drug target structure. Combining SBDD and LBDD may generate a better outcome in finding novel drug candidates (Macalino *et al.*, 2015).

Closing Remarks

SBDD is a great tool which complements experimental method in the discovery of promising drug candidates. It is now revolutionizing the discovery and development of therapeutic agents by employing the protein structure in the rational drug design. The method reduces the time required as well as failure rate in drug discovery and development. Here, SBDD workflow which includes drug target selection, binding site identification, molecular docking, and ADMET has been described. The practical illustration of molecular docking as a standard tool in SBDD has also been demonstrated.

Biographical Sketch

Ari Hardianto is a Lecturer in the Department of Chemistry, Universitas Padjadjaran, Indonesia. Ari Hardianto received his PhD from the Department of Chemistry and Biomolecular Sciences at Macquarie University. He has worked on the development of protein kinase C ϵ inhibitors using structural bioinformatics methods such as homology modeling, molecular docking, and molecular dynamics simulation. He also has research interest in immunoinformatics, chemometrics, and applications of data science in chemistry and molecular biology.

Muhammad Yusuf is a Lecturer in the Department of Chemistry, Universitas Padjadjaran, Indonesia. He is currently the head of Bioinformatics Division at the Research Center of Molecular Biotechnology and Bioinformatics, Universitas Padjadjaran. Muhammad Yusuf received his PhD from the School of Pharmaceutical Sciences, Universiti Sains Malaysia. He has worked on homology modeling, molecular docking, and molecular dynamics simulation to study the behavior of the oseltamivir-resistance neuraminidase, a drug target of influenza virus. He also has a research interest in the molecular modeling study of protein engineering, diagnostics, therapeutics, natural compounds, and rare-earth metal separation.

Fei Liu is a Senior Lecturer in the Department of Molecular Sciences, Macquarie University. She did her PhD studies in Organic Chemistry at Yale University, USA. After her PhD, she moved to Boston, Massachusetts as an NIH postdoctoral fellow to work on new biosynthetic approaches in molecular medicine at the Harvard Medical School. In 2004, Fei moved from Boston to Sydney and is currently a teaching/research academic at Macquarie. The current phase of her research focuses on developing efficient synthetic methods for accessing small molecules with useful properties in chemistry and biology. Her long-term interest in chemical proteomics along with its applications in basic biological discovery and medicine and synthesis of novel candidate cancer drugs.

Shoba Ranganathan holds a Chair in Bioinformatics at Macquarie University since 2004. She has held research and academic positions in India, USA, Singapore and Australia as well as a consultancy in industry. Shoba's research addresses several key areas of bioinformatics to understand biological systems using computational approaches. Her group has achieved both experience and expertise in different aspects of computational biology, ranging from metabolites and small molecules to biochemical networks, pathway analysis and computational systems biology. She has authored as well as edited several books in as well as contributed several articles to Springer's Encyclopedia of Systems Biology. She is currently the Editor-in-Chief of Elsevier's Encyclopedia of Bioinformatics and Computational Biology as well as the Bioinformatics Section Editor for Elsevier's Reference Module in Life Sciences.

Network-Based Analysis for Biological Discovery

Introduction

Biological processes are complex systems, involving many interactions among elementary units of a living system; these include biological macromolecules such as DNA, RNA, proteins, lipids and also small molecule metabolites. To describe such processes, a common representation is a network model in which, the participating biomolecules are represented as *nodes* and the relationships or links between them as *edges*. Proteins are the most important biological building blocks and they carry out their functions in the cells by interacting with each other. Therefore, it is not surprising that the largest amount of biomolecular interaction data is available for PPIs and consequently, the substantial chunk of biological network analysis encompasses the construction and analysis of PPI networks (PPINs). PPIs are crucial to the formation of macromolecular structures and enzymatic complexes that form the basis of nearly every cellular process ranging from signal transduction and cellular transport to catalysing metabolic reactions, activating or inhibiting other proteins and biomolecular synthesis. PPIs are thus essential to homeostasis and their dysregulation typically leads to cellular dysfunction and is often associated with various diseases. A systematic mapping of protein interactomes, i.e., the entirety of PPIs in a cell or an organism, is necessary to gain a deeper understanding of the roles of PPIs and PPINs in fundamental cellular processes. It also enables a better understanding of the genotype-phenotype relationships and the perturbations that are involved with the onset of complex diseases.

Owing to their high specificity, PPIs are also promising targets to develop drugs that attuned to specific disease-related pathways (Jubb *et al.*, 2015; Wells and McClendon, 2007; Murakami *et al.*, 2017). However, in this review, we will focus on reconstruction and analysis of PPINs and their applications in interpreting available biological data to gain a deeper understanding of cellular processes and disease mechanisms. We first discuss how experimentally defined PPIN data have been generated and utilised for knowledge discovery. Next, we will discuss why *in silico* methods for PPI characterisation are important in a PPIN-based biological research. We will conclude with how future mapping efforts focussing on a more dynamic analysis of PPINs will shape the field.

Experimental Methods to Generate Proteome-Scale Interaction Maps

A variety of powerful experimental techniques are now available to characterise PPIs. Initially, however, interactions between protein pairs were described by independent studies that employed small-scale biochemical or genetic experiments (Koh *et al.*, 2012). The steady improvements in experimental methodologies and the development of new technologies that were more amenable to PPI mapping on a larger scale, such as yeast two-hybrid system (Y2H) (Fields and Song, 1989) (see below), have allowed rapidly increasing amounts of PPIs to be characterised. However, the advent of high-throughput genome sequencing technologies and the genomics breakthrough at the turn of the millennium was a milestone that paved the way for the PPI characterisation on a proteome-wide scale. The appearance of the first draft model organism genome sequences and the accompanying collection of genome-wide open reading frames (ORFs), coupled with the availability of robust, high-throughput PPI detection methods allowed the PPI mapping to truly take off (Luck *et al.*, 2017). Thus, proteome-scale interaction maps have been generated for different proteomes using available experimental techniques that are amenable to large-scale interactome mapping (Vidal *et al.*, 2011; Huttlin *et al.* 2015; Rolland *et al.* 2014).

The experimental methods for PPI mapping can be broadly classified into two groups. The first group consists of methods that are capable of simultaneously investigating a large number of PPIs, often on an interactome scale, whereas the second group consists of methods that are more suited to deeply examine individual PPIs (Tunchag *et al.*, 2009). The Y2H system is one of the most widely used methods to map binary PPIs. Y2H is an *in vivo* method based on the reconstitution of a functional transcription factor (TF) following an interaction between two proteins and the subsequent activation of reporter genes controlled by the TF (Fields and Song, 1989). It is a scalable and relatively inexpensive method that is well suited to detecting binary interactions between proteins and therefore facilitates the characterisation of physiologically relevant PPIs. Unsurprisingly, Y2H has been the method of choice for generating proteome-wide binary interaction maps for a number of model organisms such as *E. coli* (Rajagopala *et al.*, 2014), Yeast (Uetz *et al.*, 2000; Ito *et al.* 2001; Yu *et al.*, 2008; Vo *et al.*, 2016), *C. elegans* (Li *et al.*, 2004), *Drosophila* (Formstecher *et al.*, 2005), *Arabidopsis thaliana* (Arabidopsis Interactome Mapping Consortium, 2011) and human (Vidal *et al.*, 2011; Huttlin *et al.*, 2015; Rolland *et al.*, 2014). However, Y2H suffers from a few notable shortcomings; it is less amenable to capturing PPIs involving extracellular or membrane proteins, PPIs that require proper folding as a part of protein complex subunits, or PPIs that require post-translational modifications (PTMs). To overcome the limitations of Y2H and to study different types of PPIs, several Y2H variants such as the mammalian cell-based two-hybrid assay (Luo *et al.*, 1997), the membrane-anchored two-hybrid assay (Snider *et al.*, 2010), and the three-hybrid assay (Maruta *et al.*, 2016) have been developed.

PPIs can also be mapped on an interactomic scale by Affinity Purification – Mass Spectrometry (AP-MS) that involves biochemical purification of the epitope-tagged target proteins from the cells, followed by the identification of the components of the purified protein complexes (including proteins interacting with the target protein) using mass-spectrometry analysis (Dunham *et al.*, 2012). AP-MS method has been widely used to characterise protein complexes on a large scale in different species including yeast, *Drosophila* and human (Guruharsha *et al.*, 2011; Krogan *et al.*, 2006; Ewing *et al.*, 2007). To overcome non-specific detection of co-purified proteins, two-step tandem affinity protein purification systems have been developed (Burckstummer *et al.*, 2006). This approach allows the preparation of a substantially pure target protein complex and reduces the background signals. The quantitative mass-spectrometry analysis also has been used to identify different contaminants (Trinkle-Mulcahy *et al.*, 2008). However, AP-MS data may not always detect binary interactions and often reflects only steady state PPI dynamics, thereby, potentially missing weak and transient interactions.

Another approach is to employ co-fractionation and mass spectrometry to characterise protein complexes. In this method, cellular extracts are subject to intense co-fractionation by using biochemical separation methods such as chromatography and a precise co-elution of proteins is used to determine PPIs. A distinct advantage of this method over AP-MS is that it allows a mapping of dynamic PPIs and the determination of the size of the protein complexes owing to the use of size-exclusion chromatography (Yang *et al.*, 2015). Thus, this method has been used to map protein complexes on a proteome-wide scale in different organisms such as yeast and human (Doerr, 2012; Havugimana *et al.*, 2012; Phanse *et al.*, 2016).

Eventually, a combination of different methods will provide a more comprehensive protein interaction map, since each method will likely lead to the exploration of different aspects of the interactome.

PPIN-Based Network Analysis

PPINs assembled from the experimentally characterised PPI data are an important avenue to understand the organisation of cellular events and the biology of the living systems and complex diseases. PPI data extracted from the proteomic literature and compiled within the expert-curated resources are highly useful in uncovering functional PPINs and for guiding subsequent research. However, such data are scattered across multiple databases that differ in scope and content, i.e., the type and number of PPIs they contain, the number of organisms that are covered and the experimental and computational methods that were used for PPI characterisation. Therefore, combining different PPI maps is necessary to obtain a complete view of protein interactomes (Razick *et al.*, 2008; Chen *et al.*, 2011; Chen *et al.*, 2016).

However, the combined PPI datasets will likely be noisy and include many false positives that are inherent in experimentally characterised PPIs and therefore, the assembled PPI data must be carefully assessed before using them for PPIN analyses. A relatively simple and commonly used approach is to consider only those PPIs that are determined by at least two different experimental methods or reported in the literature in two different publications (Chen *et al.*, 2016). Biophysical data from the experimentally determined structures of interacting proteins can be useful since they offer detailed insights into how PPIs are formed at the atomic scale (De Las Rivas and Fontanillo, 2010; Erijman *et al.*, 2014; Moal *et al.*, 2011, 2013), but such data are available for very few protein complexes. It is also important to view and analyse the PPIN data in the proper spatiotemporal context such as cellular/tissue specificity, protein subcellular localisation, gene expression patterns, homologous associations and PTMs (Schaefer *et al.*, 2013). A number of studies have employed PPIN analysis to probe a broad spectrum of biomolecular processes and seek answers to key biological questions (Fig. 1).

Network Topology

A typical PPIN is an undirected graph with each protein represented as a *node* and each interaction between two proteins represented as an *edge* (Fig. 1). This wiring or the connectivity of the different proteins within a PPIN is referred to as network topology. There is a strong correlation between the topological properties of a network and its functioning. Therefore, graph theory concepts such as *node degree distribution*, *betweenness centrality* and *shortest path length* have been used to identify key determinants of network function (Raman, 2010) and also to better understand network perturbations. Network ‘hubs’ are highly connected proteins with many PPIs (that is, they have a high *node degree*); they are therefore likely to have a greater influence on network functioning via multiple interactions. Network ‘bottlenecks’ are proteins with high *betweenness centrality*; they regulate the flow of signalling information across the network and therefore, represent key nodes for communication (Yu *et al.*, 2007) (Fig. 1(a)). Thus, analysing network topologies can be a source of new discoveries such as identifying novel biomarkers and potential drug targets (Csermely *et al.*, 2013; Kotlyar *et al.*, 2012; Charitou *et al.*, 2016; Gebicke-Haerter, 2016; Hakes *et al.*, 2008). Network topologies have been employed to identify novel disease-associated genes (Vidal *et al.*, 2011; Feldman *et al.*, 2008; Sarajlic *et al.*, 2013) and also to better understand the organisation of localised cellular networks. For example, Gupta *et al.* (2015) mapped the centriole-cilium protein interaction landscape by generating a PPIN consisting of > 7000 interactions and using network topology analysis, which led to the discovery of novel insights into human centrosome and cilia biology.

Understanding Disease Mechanisms Based on Network Neighbourhood

An important outcome of using PPIN topology to investigate disease mechanisms is the disease module hypothesis, which is based on the observation that genes associated with the same disease preferentially interact with each other and tend to form

Figure 1 Applications of PPIN-based analysis using large scale protein interactome maps. A reference interactome network is usually illustrated as proteins represented as *nodes* (solid circles) interacting with other proteins via PPIs represented as *edges* (solid lines). Applications of PPINs include (a) Investigating protein function and essentiality using network topology, (b) Understanding disease mechanisms by network neighbourhood, (c) Investigating the context specificity of PPIs such as in the context of cell/tissue-specific interactions (d) PPIN rewiring caused by mutation and/or disease and (e) Leveraging orthologous gene associations to map PPIs across species.

well-connected clusters in the same network neighbourhood (Barabasi *et al.*, 2011; Ideker and Sharan, 2008; Menche *et al.*, 2015) (Fig. 1(b)). The disease module hypothesis has attracted much interest from the researchers, since a given set of disease-causing genes can provide a deeper insight into related diseases. This is carried out by collating other disease-causing genes, by defining tightly interconnecting communities of functionally related or disease-related proteins and then retrieving the uncharacterised neighbouring genes connected with the initial “seed” genes by *shortest paths*. For instance, Huttlin and colleagues constructed BioPlex, a network of experimentally derived human PPIs and defined many protein communities and subnetworks that enabled functional characterisation of poorly characterised human proteins, including many with novel roles in human diseases such as cancer and hypertensive disease (Huttlin *et al.*, 2015, 2017). Rolland and co-workers also demonstrated that known cancer-associated genes are highly interconnected in the human protein interactome (Rolland *et al.*, 2014).

Context-Specificity of Protein Interactomes

Complex diseases are usually very site-specific and mostly impact specific cells and/or tissues (Goh *et al.*, 2007; Magger *et al.*, 2012). Therefore, it is necessary to examine the PPI data, in cellular and tissue context, such as cell/tissue-specific expression of proteins, the relative abundance of alternatively spliced isoforms and PTMs and their impact on the interactome of different cells and tissues. Magger and co-workers, for instance, observed that using tissue-specific PPI networks, greatly enhanced the prioritisation of candidate disease-causing genes compared with generic PPINs and also highlight novel tissue-disease associations (Magger *et al.*, 2012).

PPIN Rewiring During Disease, Mutation and Evolution

The rapid proliferation of high-quality sequence data generation using low-cost Next Generation Sequencing (NGS) experimental platforms coupled with speedy bioinformatics methods have contributed to the mapping of a large number of sequence and structural variants associated with clinically relevant phenotypes and diseases. Although there is a limited understanding of causal relationships between various mutations and diseases, it has been well established that functional variants may often impact overall protein functions including PPIs (Shameer *et al.*, 2016). Comparative PPIN analysis, therefore, offers a promising avenue to examine the genotype-phenotype relationships underlying key biological processes and the causative mechanisms of disease-

causing mutations emanating from the gain and/or loss of specific PPIs (Fig. 1(d)). Different studies involving the analysis of global PPINs in human have highlighted mutation-induced network perturbation and loss of specific PPIs that can be reliably linked with specific diseases (Rolland *et al.*, 2014; Sahni *et al.*, 2015).

PPIN rewiring has also been examined in the context of evolution and conservation of PPIs and interactions across species (Fig. 1(e)). Vo and co-workers (Vo *et al.*, 2016) constructed a high-quality binary protein interactome for *S. pombe* and implemented a framework to compare the organisation and evolution of PPINs across yeast and human. Their findings revealed extensive species-specific network rewiring and novel paradigms on network co-evolution and conservation of interacting proteins.

Despite the wealth of knowledge emerging from the analysis of increasingly available large-scale PPI data, the known protein interactomes are incomplete. This is not only due to the challenges associated with the experimental determination of PPIs, it was speculated that to obtain a comprehensive coverage of the human protein interactome, ~200 million protein pairs would need to be experimentally tested (Rolland *et al.*, 2014). Moreover, because of systemic bias, well studied genes and proteins are screened more frequently than the others and are thereby, disproportionately represented in the literature and PPI databases. This has led to other proteins, potentially the causative agents of diseases, remaining under-represented (Edwards *et al.*, 2011). This issue is particularly visible in model organisms such as rat and mouse (Murakami *et al.*, 2017) that are key for biomedical research and it is estimated that only ~10% of the human protein interactome have been characterised so far (Kotlyar *et al.*, 2015). Therefore, to generate a complete interactome, it is necessary to develop computational methods for PPI prediction to expand the coverage of PPI space and mine the protein interactomes for knowledge discovery.

***In Silico* Prediction of PPIs for PPI Network Analysis and Assessment of PPI Quality**

A wide range of *in silico* methods has been proposed to predict new PPIs and to assess the quality of existing PPIs using various features obtained from known PPIs, such as gene co-localisation, phylogenetic profiling, gene fusion, domain-domain interaction (DDI), homologous interactions, and also using various computational methods such as machine learning and text mining (Murakami *et al.*, 2017; Peng *et al.*, 2017; Keskin *et al.*, 2016). A list of the features and techniques used for the prediction and assessment of PPIs are summarised in Table 1.

In silico methods can be broadly classified into two types: Low-resolution methods that offer a simple binary classification to determine whether a given pair of proteins interact or not, and the high-resolution methods that can predict the detailed interatomic interactions between proteins (Vakser, 2014). The former can generally predict a large number of PPIs at lower cost and in much less time than experimental methods, and are also applicable to the assessment of a large number of existing PPIs. The latter can predict PPIs based on their structural and physicochemical complementarities, i.e., protein docking (Tuncbag *et al.*, 2009; Keskin *et al.*, 2016), and require protein structural information, and therefore, are expensive approaches for characterising the entire interactome.

Although recent advances in docking methodologies have produced reliable protein complex models, docking proteins with large conformational changes and/or without prior knowledge of the PPI sites (*ab initio* docking) remains a non-trivial task (Janin *et al.*, 2003; Janin and Wodak, 2007). To achieve this task, molecular dynamics (MD) simulations, which take into consideration the physical movements of atoms in proteins, have been used to elucidate the precise positions of atoms involved in the interaction; MD simulations, however, are computational resource intensive and therefore, unsuitable for whole interactome modelling.

Consequently, most of the existing *in silico* methods applicable to interactome modelling and PPI assessment rely heavily on previously known PPIs and on primary protein sequence information, which is more widely available than structural information. Below, we discuss the underlying principles of different low-resolution widely applicable *in silico* PPI prediction methods for PPIN analysis.

Table 1 A list of the features and techniques used for the prediction and assessment of PPIs

Utilised feature	Fundamental concepts
Protein structure	Structural and physicochemical complementarities.
Interologue	Orthologous PPIs among different species: If two proteins are known to interact in a species X and are conserved in a species Y, these proteins may likely interact in the species Y.
Domain information	Domain-domain interactions, since domains are directly involved in the intermolecular interactions.
Gene neighbourhood	Two proteins are likely to interact when their genes are located in the same region of genome.
Phylogenetic similarity	Functionally related proteins, i.e., interacting proteins, tend to be inherited together during evolution and co-evolve through the interaction. Thus, they have similar topological phylogenetic profiles.
Gene fusion (Domain fusion)	Separate genes can be fused to form a single chimeric gene, which is called as “Rosetta Stone”.
Function annotation	Interacting proteins tend to have shared functional annotations since they are often involved in the same biological processes.
Text mining	Grammatical rules to retrieve the co-occurrence of predefined genes or proteins, and the relationship between these entities in repositories such as literature and various databases.
Machine learning	Training a classifier on a set of known PPI data to predict whether or not a given pair of proteins interact, using informative features extracted from the training PPI dataset.

Interologue-Based Methods

Orthologous proteins are descended from a common ancestral gene as a consequence of speciation, and they are believed to retain similarity in structure and function (Fitch, 2000; Koonin, 2005; Watson *et al.*, 2005; Webber and Ponting, 2004), including PPIs. *Interologue-based methods* predict PPIs and assess the quality of existing PPIs based on the biological principle of orthologous PPIs (*interologue*) across different species, that is, if two or more proteins are known to interact in a species *I* and if they have identifiable orthologues in species *J*, the orthologous proteins may also potentially interact in species *J* (Fig. 1(e)). This approach is similar to those used for gene function annotation, where a gene function is inferred from the function of homologous genes in other species. A large amount of PPI data are currently available in public databases (Salwinski *et al.*, 2004; Licata *et al.*, 2012; Aranda *et al.*, 2010; Szklarczyk *et al.*, 2015; Chatr-Aryamontri *et al.*, 2017), where orthologous PPIs can be identified. This approach is useful in transferring the annotation of PPIs from one species to another species of interest; for example, it has been applied to predict PPIs in human cancer proteins (Jonsson and Bates, 2006). The accuracy of this approach depends on the reliability of the interactions, so it is considered to be inappropriate for the prediction of transient interactions because such interactions are poorly conserved across species (Keskin *et al.*, 2016). Thus, other features, such as domain co-occurrences, gene co-expression or functional similarity, can be integrated into this approach to assess PPIs and the co-localisation of the proteins predicted to interact, as implemented in PPI-Search (Chen *et al.*, 2009), BIPS (Garcia-Garcia *et al.*, 2012), I2D (Brown and Jurisica, 2005) and PSOPIA (Murakami and Mizuguchi, 2014) (Table 2).

Domain-Based Methods

Protein domains are independent evolutionary units, which define protein function. Multiple studies have demonstrated that domain-domain interactions (DDIs) are useful for predicting PPIs, since domains are directly involved in the intermolecular interactions (Memisevic *et al.*, 2013; Shoemaker and Panchenko, 2007). The *domain-based methods* can identify PPIs without relying on homologous interactions that exist in public databases, unlike the *interologue-based approaches*. To use DDIs for the prediction of new PPIs, most methods annotate protein sequences using domain databases such as Pfam (Finn *et al.*, 2016), SCOP2 (Andreeva *et al.*, 2014) and CATH (Sillitoe *et al.*, 2015). There are two types of *domain-based approaches* (Shoemaker and Panchenko, 2007). First type consists of the *association approach-based methods* that are based on the idea that certain domains are frequently observed in interacting proteins and therefore can be used as markers to predict new PPIs (Sprinzak and Margalit, 2001). However, this approach does not consider the relationships of all possible domain pairs in interacting pairs, and also the missing domain pairs not observed in known interacting pairs. The second type is the *Bayesian network approach*, where the interaction probabilities of all possible domain pairs are estimated using the Maximum Likelihood Estimation (Burger and van Nimwegen, 2008; Deng *et al.*, 2002). The accuracy of this approach depends on the reliability of the domain assignments, so a sufficient coverage of domain databases is necessary to obtain sufficient true positives and negatives. This approach can also be used to assess the quality of PPIs since an interaction can be deemed more reliable if they contain domain pairs found in known PPIs in the database (Ng *et al.*, 2003).

In recognition of the limitations of the *domain-based approaches*, a new set of PPI prediction methods have been developed, which are based on the principle of short co-occurring polypeptide regions as mediators of PPIs (Pitre *et al.*, 2012; Schoenrock *et al.*, 2014). A distinct advantage of these methods is that unlike the classical *domain-based approaches*, they are designed to predict PPIs solely on the basis of primary sequence and are thus, not handicapped by the absence of characterised protein domains; these methods are therefore much useful for large-scale PPI prediction. For instance, Schoenrock and colleagues (Schoenrock *et al.*,

Table 2 A selection of *in silico* prediction web servers that are useful for PPI network analysis

Available in silico prediction web servers for PPI network analysis

*These servers accept only a single protein pair per submission.

2014) designed a tool to predict human PPINs and validated their prediction results experimentally. They further employed their computationally predicted human PPINs for the prediction of gene functions and formations of PPI complexes in human diseases, some of which were validated by follow-up experimental assays (Schoenrock *et al.*, 2014).

Gene Neighbourhood-Based Methods

Gene co-localisation-based methods are based on the idea that two proteins are likely to interact when their genes are located in the same region of the genome (Tamames *et al.*, 1997). This approach requires a number of genome sequences to predict and assess PPIs using information about the conservation of gene locations, and confidence increases with increasing genome sequences. Although this approach can predict new PPIs without relying on known PPIs reported in the literature or available in databases, it would not be applicable to the eukaryotic genomes, since there is no tangible evidence that two genes which encode for interacting proteins are always co-localised within a genome. Although this approach is simple in comparison with other *in silico* approaches, it often fails to detect interactions between distantly located genes and often generates a high amount of false negatives in the eukaryotic genomes (Zahiri *et al.*, 2013).

Phylogenetic Similarity-Based Methods

There are two types of *phylogenetic similarity-based approaches*. One is the *phylogenetic tree-based approach* (also known as the *mirror tree* approach), which is based on the idea that interacting proteins tend to co-evolve through the interaction and thus have similar topological phylogenetic tree profiles (Sato *et al.*, 2005; Pazos and Valencia, 2001; Goh and Cohen, 2002), as implemented in MirrorTree (Ochoa and Pazos, 2010) (Table 2). However, when a pair of proteins co-evolve through the speciation events even if they do not interact, a large number of false positives are created due to the generation of similar mirror trees (Ochoa and Pazos, 2014). The elimination of non-specific tree similarities have been attempted by different methods, for example, the 16S rRNA tree is used as a representation of the speciation process to normalise the non-specific similarities by subtracting their phylogenetic distances from the distance matrices for a pair of proteins (Sato *et al.*, 2005; Pazos *et al.*, 2005). The second one is the *phylogenetic profile-based approach* that is based on the assumption that functionally related proteins tend to be inherited together during evolution. A phylogenetic profile represents the conservation of a certain protein in various species. Thus, if two proteins are functionally related, they are more likely to have similar phylogenetic profiles (Juan *et al.*, 2008). However, the outcomes of this approach are largely dependent on the number of the species used to construct phylogenetic profiles. Thus, this approach is not very suitable for eukaryotic proteins since there are comparatively fewer eukaryotes with complete genomic sequences than prokaryotes (Muley and Ranjan, 2012).

Gene Fusion-Based Methods

Gene fusion (domain fusion)-based approaches are based on the genetic observation that independent genes can combine or “fuse” together to form a single chimeric gene, known as “Rosetta Stone”. The method is based on the observation that two separate proteins are functionally related and are likely to interact if certain proteins in a given species consist of co-localised domains otherwise mapped to different proteins in another species (Enright *et al.*, 1999; Marcotte *et al.*, 1999; Chia and Kolatkar, 2004). Although the gene fusion is an informative feature of the functional relationships between different proteins, it requires a mapping of domain architecture across different genomes and is usually only applicable to those proteins corresponding to well-characterised protein domain families.

Function Annotation-Based Methods

Function annotation-based methods are based on the observation that interacting proteins tend to significantly share function annotations since they are involved in the same biological processes (Peng *et al.*, 2017). This method is often used to assess the quality of existing PPIs and also evaluate the reliability of different sources with experimentally determined PPIs, for example, the reliability is evaluated by computing the fraction of interacting proteins that have at least one identical function (Nabieva *et al.*, 2005). Gene Ontology (GO) can be used to define functional similarity between two proteins to assess the quality of existing PPIs (Cho *et al.*, 2007). However, this approach cannot reliably evaluate the quality of PPIs where the interacting proteins are annotated with many different GO terms (Peng *et al.*, 2017).

Text Mining-Based Methods

Text mining-based approaches use grammatical rules to retrieve the co-occurrence of predefined entities, i.e., in biology, genes or proteins, and the relationship between these entities in repositories such as literature and various databases (Papanikolaou *et al.*, 2015). An interaction between two proteins (A, B) can be ascertained if the grammatical rules, such as “A interaction verb B” or “interaction between A and B”, are used in the repositories. Although such approaches cannot retrieve PPIs not described in the repositories, they may be able to infer potentially novel PPIs in a given species based on homologous PPIs in another species. For example, this

approach has been used to automatically extract host-pathogen interactions from the biomedical literature (Thieu *et al.*, 2012), and also used in the STRING database to retrieve predicted interactions from the literature (Szklarczyk *et al.*, 2017).

Machine Learning-Based Methods

Machine learning-based methods train a classifier on a set of known PPI data to predict whether a given pair of proteins is likely to interact or not. In this approach, various types of features (descriptors) are combined and used to train the classifier, such as the positions of amino acids, the degree of the conservation and the physicochemical characteristics of proteins, the localisation of proteins, domains within proteins or the phylogenetic profile, and so on. Many different machine learning techniques, such as support vector machine (SVM), Naïve Bayes (NB), neural networks (NN), K-nearest neighbors (KNN) and random forest (RF) have been used to imbibe the informative features that can distinguish between true and false interactions. For example, the NB integrating protein domain data, gene expression data and functional annotation data has been applied to the human interactome network analysis to identify PPIs and subnetworks relevant to human cancer (Rhodes *et al.*, 2005). The KNN has been applied to identify human hereditary disease-genes based on topological features, which describe a protein in PPINs (Xu and Li, 2006). Furthermore, an ensemble learning approach, which combines multiple scores obtained from different classifiers trained on different machine learning techniques can be effective (Peng *et al.*, 2017). For example, an ensemble learning method which utilises four classifiers trained using RF, NB, SVM and multilayer perceptron (MLP, a type of NN with multi layers), has been applied to the prediction of PPIs between human and the hepatitis C virus (HCV) proteins (Emamjomeh *et al.*, 2014). The high quality of the training dataset, i.e., informative and unbiased, is crucial for accurate assessments and predictions, as well as for the evaluation of the machine learning models. The testing dataset, for example, is classified into three types by examining if the interacting partner proteins in the dataset are similar to the proteins in the training dataset or not (Hamp and Rost, 2015; Park and Marcotte, 2012). Such a classification offers an effective mechanism not only to evaluate the models but also to prepare high-quality datasets.

Different *in silico* methods based on various types of protein sequence information can be used to predict new PPIs and assess the quality of existing PPIs. Although some methods are more suitable for prokaryotes than eukaryotes, the confidence scores assigned to existing PPIs or to pairs of potentially interacting proteins can be useful to ascertain the reliability of the inferred interactomes for the subsequent PPIN analysis.

Conclusions and Future Prospects

A proteome-wide mapping of PPIs and leveraging them in PPIN-based analyses can help to gain knowledge of the genotype-phenotype relationships and the functioning of complex biological systems. Publicly available PPI data are expected to grow substantially and more comprehensive interactome maps are likely to become available in the near future. Consequently, the accuracy and efficacy of the various *in silico* PPI prediction and scoring methods will also likely improve with the increasing amounts of genomic and proteomics data that are likely to become available in the near future. As PPI mapping transitions from capturing steady state associations to dynamic interactions, it will become increasingly necessary to take additional parameters such as protein isoforms, spatiotemporal expression, localisation and interaction and perhaps even the “strength” of the PPIs into consideration to maximise the robustness of biological insights obtained from the PPIN-based analyses.

Glossary

Adjusted p-value The lowest familywise significance level, at which a certain comparison will be considered as statistically significant as part of the multiple comparison testing.

Alignment score A measure that reflects the level of similarity between sequences.

Contig Long genomic fragment, usually generated by the genome assembly software.

Copy number variation (CNV) An alteration between the number of the same genomic fragment being repeated in the genome within the population.

de Bruijn graph An approach used for *de novo* sequence assembly from short reads.

De novo genome assembly The process of constructing the genome sequence directly from the sequencing reads without any supplementary information.

Differential expression analysis A process of studying changes in expression of the genes between samples, usually under different conditions.

Duplication A rearrangement event in which a genomic fragment is copied into the same chromosome.

Edit distance The minimum number of operations (insertions, deletions or substitutions) needed to turn one sequence into another.

FASTA format A text-based file format for storing biological sequences.

GC content The percentage of cytosine and guanine nucleotides relative to the total length of nucleic sequence.

Genome rearrangement A large genomic mutation, which alternates the whole chromosomes or their long fragments.

Graph simplification The process of removing erroneous edges from the graph (usually referred to de Bruijn graph).

Hamming distance The number of positions in two strings of the same length, in which the symbols do not match.

Hybrid assembly An approach for *de novo genome assembly* using multiple different sequencing technologies simultaneously.

Indel Insertion or deletion.

Inversion A rearrangement event in which a genomic fragment is reversed within the chromosome.

k-mer A sequence of length k.

Metagenomics A field of genomics, which studies genomes of the entire bacterial communities (or other samples containing different species).

Misassembly An error in the assembly when two distant genomic fragments are joined into a single contigs/scaffold.

N50 The maximum length X for which the collection of all contigs of length $\geq X$ covers at least 50% of the assembly.

Overlap-Layout-Consensus approach (OLC) An *de novo* genome assembly method used for long sequencing reads.

Paired-end reads A couple of reads sequenced from the different ends of the same genomic fragment (typically from different strands); also can be referred to as left and right reads, or *mate reads*.

Phylogenetic tree A tree that demonstrates evolutionary relationships between selected biological species.

Read alignment (read mapping) The process of aligning sequencing reads to a longer sequence (typically reference genome) to detect the position, from which the read was originally sequences.

Read mapping See *read alignment*.

Repeat resolution The process resolving ambiguities during the assembly, which are caused by the genomic repeats.

SAM/BAM formats Formats for storing read alignment data. SAM is a text-based format and BAM is a compressed binary format.

Scaffold An ordered set of contigs, typically separated by regions with unknown bases (N).

Scaffolding The process of ordering *contigs* into *scaffolds*.

Sequence alignment The process of detecting similarities between biological sequences.

Single nucleotide polymorphism (SNP) A variation in a single position in the genome that appears in appreciable part of the population.

Strand-specific RNA-Seq A method for sequencing RNA molecules, from which it is possible to deduce the strand on which the gene is located.

String graph An approach used for *de novo* sequence assembly from short reads.

Synteny block A set of consecutive genes on the chromosome, which are typically inherited together and preserved by rearrangement events.

Translocation A rearrangement event in which a genomic fragment is exchanged with a fragment from another chromosome.

Universal single copy-ortholog A gene, which does not have paralogs and is typical for a given set of organisms.

VCF/BCF formats Formats for storing variations and mutations. VCF is a text-based format and BCF is a compressed binary format.

Introduction to Sequence Analysis

Sequence analysis is a term that comprehensively represents computational analysis of a DNA, RNA or peptide sequence, to extract knowledge about its properties, biological function, structure and evolution. To carry out sequence analysis efficiently, it is important to first understand the source of the data, i.e., the different experimental methods used for determining the biological

sequence. We then need to follow analytical strategies, depending on whether the sequence is genomic, transcriptomic or proteomic. Databases currently warehousing the enormous data on these biomolecules will need to be first checked for the presence of similar sequences, which might direct experimental assays for functional investigations. Software tools and web services are often used for carrying of the bioinformatics analysis. After analysis of DNA, RNA and protein sequences, it is important to understand how they are connected by protein to genome mapping. The small organic molecules or metabolites that are essential for organisms to live and grow also need to be studied in the context of their interaction with genes and proteins, *via* metabolic pathways. This article aims to provide an overview of sequence analysis, at the DNA, RNA and proteins levels, with metabolic pathways describing their interplay.

Nucleic Acid Sequencing

DNA Sequencing Technologies

DNA sequencing is the process of determining the order of nucleotide bases of molecules of DNA. If the DNA of the whole genome of an organism is used as the DNA of interest, then the process is referred to as genomic sequencing. This process is currently widely used both in fundamental biological research and in many applications. Information about the primary DNA sequence is a crucial piece of data used in such areas of research as medical studies, gene therapy, drug development, evolutionary studies, agriculture, improvement of nutritional quality, biotechnology, forensic and many other.

First-generation sequencing

The era of DNA sequencing began about 30 years ago, when two methods of primary DNA structure determination appeared almost simultaneously. The one developed by A. Maxam and W. Gilbert at Harvard University was based on the use of chemical modifications of DNA. The other method was published by F. Sanger and A. Coulson from Cambridge and is called the chain-termination method. These methods were named 1st generation sequencing (Heather and Chain, 2016).

And although over time, both the Gilbert and the Sanger DNA sequencing methods have gone through a number of significant changes (one of which was the automation of the Sanger DNA method that assured its wider application), first generation sequencing methods continued to remain labor intensive, had a low throughput speed and were very expensive. To overcome these limitations and in response to the National Human Genome Research Institute (NHGRI) call to lower the cost of sequencing of an individual human genome to \$1000, with an intermediate goal of reducing the cost of sequencing a mammalian-sized genome to \$100,000, next generation sequencing technologies (NGS) were rapidly developed and began to be used in pyrosequencing, base-by-base sequencing by synthesis (SBS), sequencing by ligation, nanopore sequencing, and single-molecule sequencing by synthesis in real time strategies.

These newest sequencing technologies that are currently at different stages of development and implementation can be split into two groups: Second generation sequencing and the third generation approaches.

Second-generation sequencing

Compared to the traditional Sanger sequencing, the greatest advantage of the second generation sequencing is a very high level of parallelization: up to 10^7 reactions in one experiment. In addition, the minuscule volume of the individual wells (picoliters), within which the sequencing reactions are run and the high data density (10,000 times higher, than in case of the latest microelectrophoresis-based capillary instruments) significantly decrease the volume of reagents needed to perform the reactions. Another positive aspect of the second generation methods is the ability to circumvent DNA cloning and propagation in *Escherichia coli* cells, thus avoiding the problems of biased genome coverage due to the presence of genomic areas, which are hard or even impossible to clone in *E. coli* (so called unclonable areas). The downside of these technologies, as compared with the Sanger approach, however, is the length of the produced reads.

The 454 Genome Sequencer 20 System instrument (the first commercial NGS platform) produced reads of about 110 bp. The latest GS FLX Titanium chemistry (Margulies *et al.*, 2005) has managed to increase read length up to 1 kb (454 Life Sciences was shut down in 2013 and 454 sequencing instruments are not supported any longer). Meanwhile, technologies using SBS and sequencing by ligation (Applied Biosystem SOLiD; polony-based approaches) produced reads of only 25–50 bp long (Shendure *et al.*, 2005; Valouev *et al.*, 2008). This meant that although 454 sequencing has been successfully applied to de novo genome sequencing resulting in a gapped assembly with an error rate of about 1/3000–1/5000 bp, the ultra-short reads produced by Solexa technology appeared to be of use for resequencing purposes only, in this case a high-quality reference sequence would be present for alignment. The use of 25–50 bp reads for de novo genome sequencing appeared to be very problematic.

After being acquired by Illumina, the Solexa technology was renamed to Illumina technology. This approach uses the SBS sequencing to generate massively parallel genomic data and detect single bases as they are incorporated into growing DNA strands. Read lengths vary from 100 bp to 300 bp depending on the sequencing instrument used (MiSeq, NextSeq 500, different HiSeq). The low error rate of Illumina reads ($\leq 0.1\%$) makes this sequencing technology very attractive for a number of applications including de novo genome assembly.

Ion Torrent is yet another NGS approach (Rothberg *et al.*, 2011). It uses the semiconductor sequencing technology of SBS. The Ion PGM sequencer detects changes in pH when a nucleotide is incorporated into the DNA molecules and a proton is released.

This technology produces reads of 400 bp long with about 1% error rate, allowing single nucleotide polymorphism (SNP) detection as well as whole genome assembly.

The second Ion Torrent instrument released in 2012, the Ion Proton, produces shorter reads (200 bp), but provides 10 times larger (~10 Gb) output than its predecessor. The read length provided by recently developed Ion S5 and Ion S5 XL Systems (www.thermofisher.com) is ranging from 200 bp to 600 bp depending on the chip type and the output can be as high as 10–15 Gb.

Third-generation sequencing

Among the numerous methods on the drawing board, special attention should be given to real-time sequencing of DNA molecules. Such methods use very small amounts of genomic DNA and require supersensitive detection methods. The success of these methods wholly depends on the quality of the genomic DNA used in the experiment: if the DNA is damaged while being isolated, the resulting sequence will be corrupt. In theory, the read length produced by this type of technology should be equal to that of a full genome.

PacBio (SMRT) sequencing is one of the first real-time single-molecule sequencing techniques capable of generating long reads (10–15 Kb) without requiring any amplification steps. Additionally, its unique ability to distinguish methylated bases from normal nucleotides (Levene *et al.*, 2003) opens up the possibility of studying the epigenetic potential of different organisms. Read error rate is high, but errors are random and thus can be corrected via an increase in coverage. Long reads play a crucial role in the gap closing step of the whole genome assembly and PacBio gave genome finishing, a step that for several years was set aside as time-consuming and not cost efficient, a much needed boost.

The UK company Oxford Nanopore Technologies developed a next generation sequencing approach based on nanopores. The MinION system allows to produce more than 3 Gbp of data from a single run. The resulting reads are of a variable length and can be up to 900,000 bases long. The current error rate of nanopore reads is 5%–15%. It was observed that this technology produces systematic sequencing errors, which end up being more challenging to correct bioinformatically than random ones.

The list of companies and university-based groups of researchers working on improving sequencing technology goes on and on. Some of them have already managed to achieve commercial success, others are still only working on approaching this goal and many have either already failed to do so or will end up failing eventually (Lapidus, 2015). In most cases a combination of different sequencing approaches allows to produce a high-quality sequence fairly quickly and at very low cost.

Rna-Seq

RNA molecules play a significant role in all living cells. Messenger RNA (mRNA) for example is responsible for translating the genetic information stored in DNA into proteins composed of different combinations of 20 amino acids, each of which has its own type of transfer RNA (tRNA) that binds and transports them to the growing polypeptide chain when needed. Ribosomal RNA (rRNA) is an integral part of both large and small subunits of ribosomes – A complex molecule responsible for protein synthesis in cells.

Transcriptomics allows to study the nature and amount of each of the RNA molecules in a given cell under a specific condition and at a given moment. The RNA sequencing (RNA-seq) approach uses next-generation sequencing (NGS) to perform direct sequencing of cDNA fragments (Hrdlickova *et al.*, 2017).

RNA-seq can detect: (i) Gene expression level; (ii) transcript abundance; (iii) alternative splicing that causes transcriptional diversity in eukaryotes; (iv) different isoform usage; (v) single nucleotide variations; (vi) fusion genes; (vii) post-transcriptional modifications. It can identify genes, exons, splicing events, ncRNAs, novel genes or transcripts.

A typical RNA-Seq experiment consists of RNA isolation and purification, assessment of the RNA purity and yield, enrichment of target RNAs (through polyA selection, size selection, or removal of non-target sequences through hybridization to probes), fragmentation of RNA, amplification, sequencing, followed by data analysis that in its turn includes quality control, read alignment to a reference genome or known transcripts, transcript quantification and *differential expression analysis* (Kukurba, 2015).

Most of the methods used for RNA-seq data analysis rely on well-annotated reference genomes and on accurate gene models of model organisms. The *de novo* transcriptome assembly approach helps to reconstruct the sequence of the expressed transcripts and is used when reference genomes are not available.

Sequencing Data Formats

The simplest and one of the most common formats for storing nucleic and amino acid sequences is the *FASTA format* (see “Relevant Websites section”). Typically FASTA files have “.fasta” or “.fa” extensions, but other extensions, such as “.fna” for nucleic sequences and “.faa” for proteins are also sometimes used. A single entry in a FASTA file contains the sequence name (sequence ID) and the sequence itself. Sequence names may also contain some meta information, such as for example sequence length. When the sequence is long, it is stored in multiple lines for added legibility. FASTA files can contain an unlimited number of sequence entries.

Sequencing reads can also be stored in the *FASTQ format* (see “Relevant Websites section”) that contains information about reads quality in addition to read sequence and read ID. In the process of sequencing, the sequencer can estimate the probability of each nucleotide being detected incorrectly. The decimal logarithm of the error probability is then rounded to the nearest integer,

added to a fixed offset and written to the FASTQ file as the corresponding ASCII character. However, there are several different formats for storing quality values, which vary by offset values and the way the error probability is converted to an integer number. Read ID in FASTQ file may contain additional information about the reads. For example, Illumina sequencer stores flowcell lane number, tile number, coordinates of the cluster and the information about read pairing (if reads are *paired*).

There are two possible ways to store *paired-end reads* in FASTQ files. The most common method stores left and right reads in the two separate files. The order of the reads in both files should be the same, i.e., first read from the file with left reads is a mate for the first read from the file with right reads. Paired reads can also be saved into a single file (called *interlaced FASTQ file*), in which left and right reads are placed one after another.

Since both FASTA and FASTQ formats are text formats, they typically require a huge amount of disk space. To save space, FASTQ files are usually either compressed using standard archiver software, or converted to SRA or unmapped BAM binary formats.

Beside FASTA/FASTQ, there exists a large variety of file formats suitable for storing supplementary information, such as sequence alignments, genomic variations and genome annotation. Some of these formats will be described further throughout the article.

Analyzing Genomic Sequences

Sequence Alignment

Classic alignment algorithms

Sequence alignment is the process of comparing and detecting similarities between biological sequences. What “similarities” are being detected will depend on the goals of the particular alignment process. Sequence alignment appears to be extremely useful in a number of bioinformatics applications.

For example, the simplest way to compare two sequences of the same length is to calculate the number of matching symbols. The value that measures the degree of sequence similarity is called the *alignment score* of two sequences. The opposite value, corresponding to the level of dissimilarity between sequences, is usually referred to as the *distance* between sequences. The number of non-matching characters is called the *Hamming distance*. [Fig. 1](#) shows an example of two sequences with Hamming distance ([Bookstein et al., 2002](#)) equal to 3.

It is, however, worth noting that comparing sequence characters position by position as described above can barely be referred to as alignment process, since it does not take into account such typical biological events as deletions and insertions. The classical notion of sequence alignment includes calculating the so called *edit distance*, which generally corresponds to the minimal number of substitution, insertions and deletions needed to turn one sequence into another. [Fig. 2](#) demonstrates an example of two sequences with edit distance equal to 3.

The problems of computing edit distance and various types of sequence alignment have exact solutions, e.g., ([Smith and Waterman, 1981](#)) and ([Needleman and Wunsch, 1970](#)) algorithms. Since these algorithms were initially developed for protein-protein alignment and later adapted for DNA sequence alignment, they are described in the section ‘Protein-protein alignment’. In most real-life cases, however, these algorithms appear to be impractical for DNA alignment due to their running time and memory requirements.

BLAST and similar database search methods

To overcome the limitations of the classic alignment algorithms, which are usually used for rather short sequences, new methods and heuristics were developed. By heuristic algorithm we imply a non-exact solution, which works faster than exact algorithms (sometimes much faster) and provides biologically meaningful results.

Undoubtedly, the most popular sequence alignment tool in bioinformatics is the BLAST algorithm ([Altschul et al., 1990](#)) and its variations, such as BLASTN ([Acland et al., 2014](#)) and MegaBLAST ([Morgulis et al., 2008](#)). The paper that describes the first version of the BLAST algorithm now has more than 60 thousand citations and the count keeps going up. Various modifications of the BLAST algorithms are used for aligning amino acid sequences to nucleic sequences (tblastn) and vice versa (blastx). BLAST is

ATTCGGA-CT-A
```

Fig. 2 Example of two sequences with edit distances equal to 3.

widely used on the NCBI web site for searching sequences in various databases, such as 16s rRNA sequences and the nucleotide collection (all assembled genomes).

Beside the BLAST family algorithms, multiple alignment methods for various goals were developed during the past 20 years. Depending on the biological problem and alignment objective, different methods employ different algorithms and heuristic ideas, such as suffix trees and suffix arrays, k-mer indexing, seed-and-extend approaches and Hidden Markov Models. More information about specific sequence alignment algorithms can be found in Section “De Novo Transcriptome Assembly” (protein sequence alignment) and Section “Sequencing Data Formats” (mapping sequencing reads to the reference genome).

Comparative genomics

Nucleic sequence alignment algorithms are widely used in comparative genomics and phylogenetic studies. Comparative genomics studies similarities between two or more genomes at the level of large *rearrangement* events, such as *inversions*, *duplications*, *translocations*, large insertions and deletions. Since the comparative genomics usually does not take into account small structural variations and *single nucleotide polymorphisms* (SNPs), it requires a specific kind of alignment software. These methods typically detect *synteny blocks* – long sequences shared between genomes being compared. Indeed, those sequences may have differences at the nucleotide level, but are still highly similar overall. The genomes are then represented as a sequence of synteny blocks and rearrangements are detected (Hannenhalli and Pevzner, 1999).

Phylogenetic studies use various multiple sequence alignment methods to detect the level of sequence dissimilarity. The distance between compared sequences is used to construct *phylogenetic trees*, in which the length of the branches typically correspond to the distance between analyzed sequences. To construct a biologically meaningful and realistic tree, various clustering methods can be used as well as different sequences may be provided as input (Felsenstein, 1981; Kumar et al., 1994). Phylogenetic studies can be done using whole genomes and rearrangement events, genes and proteins sequences, or even SNPs for closely related organisms.

Preprocessing Sequencing Data

Quality control of sequencing data

Regardless of what technology, protocol or sample was used to generate sequencing data, quality control remains an integral part of every experiment. When performed correctly during the early stages of a project, quality control helps save time and thus, money. There have been many cases when false conclusions were made due to the poor quality of initial data, and, as a known saying states, “garbage in – garbage out”, meaning that great results do not come from low-quality data.

FastQC is one of the most popular tools for basic quality control of different kinds of sequencing data (Andrews, 2010). FastQC does not require any additional data, such as a reference genome, and the QC is performed based on just a FASTQ file with sequences and corresponding quality values. Below we will take a look at several important statistics produced by FastQC, how to interpret them and what the differences between high- and low- quality data are.

The first and one of the most important plots is the per base sequence quality plot. It demonstrates the average quality value amongst the reads. Illumina reads typically have lower quality and a higher number of sequencing errors towards the end of the read. Fig. 3 demonstrates the plot of a per base sequence quality distribution of a normal Illumina dataset, while Fig. 4 gives an example of low-quality Illumina reads and shows the significant drop in the average quality towards reads’ end.

One of the basic, but very important nucleic sequence properties is the *GC content*. It is calculated as the total number of guanine and cytosine nucleotides relative to the total sequence length. The per sequence GC content plot is usually used to detect the presence of contamination in the sample. In case of non-contaminated sequencing data, the GC content distribution is typically bell-shaped and matches the theoretical distribution (Fig. 5). In the presence of contamination this distribution may contain several separate peaks, each of which would correspond to a different genome with different GC content (Fig. 6).

The following group of statistics and plots is typically used to detect a very common problem – The presence of sequencing adapters in the reads. These statistics include per base sequence content, adapter content, k-mer content and overrepresented sequences. The figures below demonstrate how sequence content plots look when working with clean data (Fig. 7) and with reads containing adapters (Fig. 8).

Adapter and quality trimming

As was demonstrated, sequencing adapters and low-quality ends (for Illumina reads) are the common problems that often arise when analyzing sequencing data. Both of them may significantly affect performance and the quality of the results generated during the next steps of the analysis, such as, for example, genome assembly. Therefore, during the preprocessing step low-quality ends are clipped and the adapters are removed.

One of the tools used for read trimming is called Trimmomatic (Bolger et al., 2014). This tool is capable of clipping reads using quality values and removing adapters from both single-end and paired-end reads. One of the most useful methods for trimming reads is the detection of low-quality ends based on the average quality in the sliding window of a fixed size. A read is cut once the average quality in a window drops below a given threshold. Fig. 9 demonstrates what the per base sequence quality plot looks like once the reads have been trimmed (plot for original reads is shown on Fig. 4). To remove the adapters from the reads a FASTA file with the adapter sequences needs to be fed into Trimmomatic. Other adapter-removing tools, such as cutadapt (Martin, 2011) or NxTrim (O’Connell et al., 2015), can also be used.

Fig. 3 Per-base sequence quality plot for normal Illumina reads.

Filtering contamination

Another typical problem for sequencing data is contamination – the presence of reads from the genomes of species you did not intend to sequence. Read contamination usually occurs when the sample has not been completely purified and contains the DNA of other organisms. As mentioned above, in cases when the unwanted genome contaminant has a different GC content, its presence can be easily detected using the per sequence GC content plot in FastQC. Otherwise, contamination may be detected using *read alignment* (see next section) or once the genome has been assembled.

In order to filter out the contaminants, one needs to have a database to screen the reads against. In most cases, a reference genome of the suspected contaminant can be used for this purpose. Contaminant reads can be cleaned using read alignment or using a simple tool called *bbduk* from the *bbtools* package (Bushnell, 2014).

Mapping Sequencing Data

Goals and problems of short reads alignment

The problem of aligning a read to a reference genome can be reformulated as an attempt to find the position, from which the read was originally sequenced. *Read alignment* (or *read mapping*) is essential for many biological and medical applications, such as detecting genomic variations in the sequenced organism and phylogenetic studies.

Although both the local and the global alignments have exact solutions, these algorithms have a quadratic running time and memory consumption, which makes them inapplicable for read alignment due to the large size of genomic sequences (e.g., human genome is almost 3 Gbp long). Additionally, a single sequencing library may contain up to 100 million reads. Thus, in order to perform read alignment for the entire dataset in an observable amount of time, every separate read alignment has to be performed extremely efficiently. Several techniques used to speed up read alignment are discussed in the next section.

Fig. 4 Per-base sequence quality plot for low-quality Illumina reads.

The problem of read alignment is further complicated by the differences between the reference genome and the genome being analyzed, sequencing errors and genomic repeats. Reads corresponding to repetitive regions can be mapped to several genomic locations and are typically ignored.

In this section we discuss several approaches and tools that are designed for the purpose of aligning reads obtained with different sequencing technologies.

Alignment file formats

Files containing information about the alignment of reads to the reference sequence are typically stored using a specific file format called SAM. SAM files start with a header, which contains all the necessary supplementary information (e.g., lengths of chromosomes in the reference genome). Information about each read alignment is written as a separate line and contains such information as: The position and the strand of the read on the chromosome, name of the chromosome, read ID, the read sequence itself and the corresponding quality string, the information about the mate read (for paired reads) and other supplementary data. Complete information can be found in the SAM format specification.

Since SAM is a text format, it may require a huge amount of disk space, especially when the input files contain hundreds of millions of reads. To reduce disk usage, the binary BAM format was implemented. Typically, BAM files occupy up to 5 times less spaces than SAM files with the same amount of information. SAM/BAM files can be manipulated, converted and processed using a popular package called samtools (Li *et al.*, 2009).

Short read alignment

Modern short read alignment software is based on the same principles as internet search engines – Indexing the content to enable faster query search. Preprocessing of long genomic sequence allows to rapidly search for any of the reads. The genome is often indexed using a suffix array, the Burrows-Wheeler transform, the *FM-index* (Ferragina *et al.*, 2004) or a variation of these algorithms. Since the size of a genome may be large, the preprocessing step may take a significant amount of time, but on the up side, it

Fig. 5 GC content plot for normal Illumina reads.

needs to be computed only once. Once the index is computed, the read alignment itself can be performed quickly and in parallel, which allows to process reads simultaneously using multiple threads.

The most popular tools for aligning genomic reads are Bowtie2 (Langmead and Salzberg, 2012), various bwa algorithms (Li and Durbin, 2009; Li, 2013), bbmap (Bushnell, 2014) and others. In the case of Ion Torrent sequencing technology TMap can also be used as an alternative. Although comparisons demonstrating the differences in speed and accuracy between a number of popular aligners were published, the final selection of the read alignment software typically comes down to a personal preference based on individual experience.

Variation calling

The main application of short read alignment is detecting different types of genomic variations: *single nucleotide polymorphism* (SNP) sites, small insertions and deletions (*indels*), *copy number variations* (CNV). These kinds of events may have significant biological meaning and thus are of high interest as topics of investigation. For example, a change of single nucleotide in *rpoB* gene of *Mycobacterium tuberculosis* makes it resistant to Rifampicin.

To perform a variation calling, read alignments are sorted, the BAM files are then indexed, the reads are piled up and the variations are detected by comparing them to the reference sequence. Discovered variations are then filtered based on the specific parameters of the final objective. Filtering criteria may depend on such factors as, for example, the average coverage depth of the sequencing library or the organism ploidy. Details on the different variation calling pipelines can be found in the documentation for the Genome Analysis Toolkit (McKenna *et al.*, 2010).

Discovered genomic variations are typically stored in the VCF file format, or in the compressed BCF binary format. The vcftools toolkit is often used to filter and process these files (Danecek *et al.*, 2011). However, the process of calling SNPs on its own does not provide any biologically meaningful insights. In order to understand the effect of the discovered mutation, SNPs need to be annotated. Annotation of the genomic variations can be performed, using several existing databases (e.g., dbSNP, Ensembl Variation) and tools (e.g., SNPeff (Cingolani *et al.*, 2012), ANNOVAR (Wang *et al.*, 2012)), the selection of which will depend on the types of mutation discovered and its expected effect. *De novo* annotation is also possible, but typically requires a large number of samples to be examined in order to determine the associations between the particular variation and the studied effect (e.g., antibiotic resistance).

Fig. 6 GC content plot for contaminated Illumina reads.

In addition, once the variations are called, it may be useful to visualize them in a genome browser. Genome browsers are designed to display various genomic features along the chromosomes, such as genes and isoforms. Each genome browser is typically developed to address one particular need and is not universal. For example, to view and examine SNP sites a simple browser called Tablet ([Milne et al., 2009](#)) may be used. Alternatively, more sophisticated browsers, such as IGV ([Thorvaldsdóttir et al., 2013](#)) or UCSC ([Kent et al., 2002](#)) genome browsers can be used.

QC using read alignment

Another possible application of read mapping is an additional QC of sequencing library and calculation of various statistics that cannot be computed without a reference genome. For, example, the number of unaligned, uniquely aligned and multiply aligned reads, fraction of the genome covered and substitution error frequencies.

Read alignments may also be used to estimate coverage depth along the genome. [Figs. 10](#) and [11](#) show two coverage plots for different E.coli sequencing datasets. On both plots each dot represents an average coverage depth in the window of 1 kbp. [Fig. 10](#) demonstrates the coverage distribution for a conventional isolate dataset (uniform coverage distribution and more than 99% of genome covered), while plot on [Fig. 11](#) is constructed using the single-cell MDA-amplified sequencing data (only 96% of genome is covered and coverage depth is highly uneven due to non-uniform amplification process).

Another useful statistic that can be obtained via read alignment is the information about the insert size distribution. [Fig. 12](#) demonstrates the insert size distribution of an E.coli dataset with an average insert size of 215 bp and a standard deviation of 10 bp.

Plots and statistics shown above may be used to identify problems that cannot be detected using basic QC analysis, such as, for example, problems with size selection and coverage gaps.

Long error-prone read alignment

Reads generated by PacBio and Oxford Nanopore technologies significantly differ from those generated by the previous NGS technologies in terms of read length and accuracy. Alignment tools listed in the previous sections were designed especially for short reads with a rather low error rate and did not perform well out-of-the-box.

Fig. 7 Per-base sequence content for normal Illumina reads.

Therefore, several new tools were developed for alignment of long error-prone reads, e.g., GraphMap (Sović *et al.*, 2016) and minimap (Li, 2016). The later one is known for mapping reads without outputting actual alignments, which dramatically improves its performance. In addition, the bwa mem algorithm was modified and tuned to support the new family of sequencing technologies. However, due to an extremely high error rate, PacBio and Oxford Nanopores are not the best pieces of technology for calling SNPs and other small variations.

De Novo Genome Assembly

One of the first applications that genome sequencing was intended for is the *de novo genome assembly*. Currently, the problem of assembling a genome from scratch still cannot be considered as completely solved. Even now, in the age of biotechnological and computational progress, a path from the raw biological sample to the finished genome may require years of work and substantial financial resources.

The problem of *de novo* assembly is one of the most popular and algorithmically challenging in computational biology. Dozens of tools were developed during the sequencing era, and yet none of those tools can be named as the best genome assembler in the world for all cases. It is hardly possible to create a universal genome assembler due to the differences in the genomes being sequences, research goals and sequencing technologies.

Despite all recent advances in biotechnology and bioinformatics, it is rarely possible to generate a complete assembly of all chromosomes from raw reads. The key reasons are (i) the presence of genomic repeats and (ii) various sequencing errors and biases. Assembly tools typically generate long genomic regions called *contigs* (stored in FASTA format). The contigs can be further ordered and joined into *scaffolds*, even when the exact genomic sequence and distance between them is unknown. The unspecified nucleotide is usually denoted as an N symbol in the output FASTA file. The scaffolding step is typically performed by long-range sequencing libraries, e.g., mate-pairs.

De novo assembly using long reads

The most intuitive way of solving *de novo* genome assembly problem is to join overlapping reads with each other one by one – in the same way as jigsaw puzzles are assembled. The approach that implements this simple idea is called *Overlap-Layout-Consensus*

Fig. 8 Per-base sequence content for Illumina reads containing adapters.

(OLC), because it consists of the three consecutive stages. During the first step possible overlaps between all reads are detected, which is typically done using BLAST or similar algorithms. Afterwards, the algorithm constructs an overlap graph in order to determine the layout of the reads, which is then used to compute the consensus sequence and to obtain the resulting contigs. The OLC approach was implemented in multiple popular assembly tools, e.g., Celera (Myers *et al.*, 2000).

As was previously described, Sanger sequencing yields accurate reads up to 1 kbp, typically with low coverage. These characteristics allow to assemble Sanger reads using the OLC approach, which was successfully carried out in multiple groundbreaking genome assembly projects, such as the human genome project. Currently, genomes assembled from Sanger reads with the OLC approach remain the golden standard of genome assembly.

However, this algorithm requires significant computational resources for detecting overlaps between all reads. Although several optimizations can be done to speed up this step, it is still hardly possible to calculate all overlaps for high-covered NGS datasets.

The OLC approach was brought back to life by the recent emergence of the third-generation sequencing technologies – PacBio and Oxford Nanopore. Although Sanger sequencing differs significantly from these novel technologies in terms of error rate and read length, a modified OLC approach appeared to be very useful for their assembly. The main modification compared to the previous implementations of OLC was introduced in the overlap stage, which now implies the alignment of the reads with an extremely high error rate. OLC was successfully reused in such *de novo* assemblers as Canu (Koren *et al.*, 2017) and miniasm (Li, 2016).

De novo assembly using short reads

During the NGS era, sequencing became cheaper, and therefore available to more researchers worldwide. At the same time, it brought multiple algorithmic challenges to computational biology. The problem of *de novo* genome assembly was not an exception. The OLC approach appeared to be impractical for NGS data due to the extreme amount of reads and their short length.

Pevzner *et al.* (2001) proposed to apply the *de Bruijn graph* to the problem of *de novo* genome assembly from short reads. To construct a de Bruijn graph the reads are shredded into a set of smaller sequences of a fixed length k (called *k-mers*), which represent vertices of the graph. In comparison to the overlap graph, the process of constructing a de Bruijn graph does not include

Fig. 9 Per-base sequence quality plot for quality-trimmed Illumina reads.

Fig. 10 Coverage depth along the genome for isolate *E.coli* dataset.

Fig. 11 Coverage depth along the genome for MDA-amplified *E.coli* dataset.

Fig. 12 Insert size distribution for isolate *E.coli* dataset.

read alignment stage, which greatly reduces running time. Since each k-mer is stored only once, the de Bruijn graph approach appears to be more memory-efficient than OLC and therefore suitable for high-coverage datasets with millions of reads.

Although the idea of using the de Bruijn graph was a breakthrough and revolutionized the field of *de novo* genome assembly, its application to real data necessitated the development of several additional algorithms and heuristics. For example, the de Bruijn graph approach appeared to be sensitive to sequencing errors. Each substitution error in a single read creates a number of erroneous non-genomic k-mers, which have to be removed. The process of cleaning the graph from these erroneous k-mers is called *graph simplification*. Once the graph is simplified, *repeat resolution* and *scaffolding* steps are performed to extract contigs and scaffolds from the graph with the help of, for example, read-pairs (Bresler *et al.*, 2012; Pribelski *et al.*, 2014). The de Bruijn graph approach is implemented in many state-of-the-art genome assembly tools, such as Velvet (Zerbino and Birney, 2008), ABySS (Simpson *et al.*, 2009), SOAPdenovo (Luo *et al.*, 2012) and SPAdes (Nurk *et al.*, 2013).

It is worth noting, that later, in 2005, another similar concept called *String graph* was proposed by Myers (2005). In 2010 it was successfully adapted for use with real data and implemented in the SGA tool (Simpson and Durbin, 2012).

Hybrid assembly

Emergence of novel sequencing technologies also brought the possibility to perform *hybrid assembly* – A process of assembling genomes using reads from different sequencing technologies simultaneously. Hybrid assembly may be useful when long-read libraries have low coverage depth (e.g., less than 20x), which may be insufficient for constructing a reliable consensus string using the OLC approach due to the high error-rate of the reads.

Currently, there are two distinct approaches for utilizing short and long reads simultaneously. In the first approach, short accurate NGS reads are assembled using existing assembly tools to obtain accurate contigs with a small number of substitution and indel errors. Afterwards, long error-prone reads are mapped to these contigs and used for repeat resolution and scaffolding. Since PacBio and Oxford Nanopore technologies are capable of yielding reads up to hundreds of kilobases long, they can be useful for resolving long repeats and closing gaps between Illumina contigs. Some algorithms for hybrid assembly also consider aligning long reads directly to the edges of the de Bruijn graph and perform repeat resolution without explicitly outputting the contigs (Antipov *et al.*, 2015; Wick *et al.*, 2017).

Another approach consists of mapping short accurate reads (typically Illumina) onto long error-prone reads in order to correct sequencing errors in the long reads. Once errors are corrected, the long reads can be fed into a conventional OLC assembler to generate long and accurate contigs (Koren *et al.*, 2012).

Genome assembly evaluation

Assessing the quality of the assembled contigs and scaffolds is an important step for both assembly software developers and their users. By evaluating assemblers on various datasets the developers may gain a better understanding of the disadvantages and weak points of their software, improve it and benchmark against other tools to convince the scientific community that their assembler performs better on a specific variety of datasets. This also means that researchers involved in projects requiring genome assembly now face the problem of having to choose the best assembly tools for their particular needs.

One of the first attempts to benchmark genome assembly tools was made by the organizers of the Assemblathon competitions, who suggested the idea of assembling several datasets and then comparing the results submitted by the different teams. Assemblathon 1 offered simulated data, while Assemblathon 2 provided real sequencing data from three vertebral genomes. The resulted contigs were compared using multiple different metrics and the results were then published (Earl *et al.*, 2011; Bradnam *et al.*, 2013).

Benchmarks of various assemblers were also performed by the developers of the assembly tools. However, since until recently no standard tool for evaluating genome assembly quality existed, most of these comparisons were made using custom in-house scripts. In addition, to justify the research, in most cases dataset selection was subjective and the benchmarks typically revealed that the assembler described in the paper outperforms all other tools. However, several benchmarks were performed and published by independent research groups with the goal of identifying the strong and weak points of different genome assembly software (Salzberg *et al.*, 2012; Magoc *et al.*, 2013).

In 2012 GAGE (Salzberg *et al.*, 2012) and QUAST (Gurevich *et al.*, 2013) tools were developed to allow researchers to perform genome assembly quality evaluation on their own. These tools are mostly designed for assessing assemblies of model organisms, i.e., when the reference genome is known. Reference-based quality evaluation allows to perform an excessive analysis of the assemblies by providing a number of informative metrics, such as the fraction of the genome covered, *misassemblies* statistics as well as mismatch and indel error rates.

While reference-based assembly evaluation is useful for testing and comparing genome assemblers, *de novo* evaluation is an integral part of the genome assembly projects. In general, there are three different approaches for reference-free assembly quality assessment. The first one includes calculation of basic statistics (e.g., total assembly length, *N50*) and is useful for initial quality control of the assembly. Another method relies on mapping the raw reads back to the assembly and estimating the likelihood of this particular assembly being generated by the given reads (Hunt *et al.*, 2013). The last group of methods involve counting genes in the assembled sequences. The BUSCO tool (Simão *et al.*, 2015) is designed for detecting the presence of *universal single-copy orthologs*, typical for the specified kingdom, phylum or class. Such tools as GeneMark (Lukashin and Borodovsky, 1998) and Glimmer (Delcher *et al.*, 1999) identify genes *de novo* using Hidden Markov Models (see Section “Genome Annotation” for more information).

Assembly of microbial genomes

Microbial genomes are known for their rather simple repeat structures (compared to the eukaryotic genomes) and therefore are easier to assemble. Since most of the repeats in bacterial genomes do not exceed 7 kbp in length, it is usually possible to assemble a complete bacterial genome with the help of either a mate-pair library (Vasilinets *et al.*, 2015) with a large insert size or long-read sequencing data (Antipov *et al.*, 2015; Wick *et al.*, 2017). Current Illumina Nextera Mate-Pair protocol allows to obtain a complete bacterial genome using only a single short-read sequencing library (Vasilinets *et al.*, 2015). At the same time, a single PacBio or Oxford Nanopore library with a decent coverage depth (e.g., higher than 20x–30x) also allows to obtain a complete bacterial genome in most cases.

To generate a sequencing library for a prokaryotic organism millions of identical cells are needed. However, nowadays most of known bacteria cannot be cultivated in the lab. To generate enough genomic material for the sequencing experiment, bacterial genome from a single cell can be amplified using for example the Multiple Displacement Amplification method (Lizardi and Yale University, 2000). Compared to the conventional isolate datasets, the reads obtained via the MDA technology typically have a highly uneven coverage depth across the genome, which complicates the assembly process. To address the problem of single-cell bacterial assembly SPAdes (Nurk *et al.*, 2013) and IDBA-UD (Peng *et al.*, 2012) assemblers were developed. Recently, a first bacterial genome was completely assembled and finished using only single-cell sequencing data (Woyke, 2010).

Assembling metagenomes

In real life, bacteria typically exist within large communities that may contain thousands of different species. Sequencing and studying the whole community at once is called *metagenomics*. Until recently, metagenomic studies mostly included such research goals as detecting the variety of species (e.g., using 16s rRNA genes) and their abundances within the specific community. The development of MEGAHIT (Li *et al.*, 2015) and metaSPAdes (Nurk *et al.*, 2017) assemblers allows to obtain decent bacterial assemblies from metagenomic datasets.

Metagenome assembly is characterized by such challenges as the presence of related strains within the community, conservative genomic regions shared between different species and uneven coverage depth due to variations in the abundances of the different bacteria in the sample. In addition, metagenomic datasets typically contain enormous amount of reads to capture genomic information for underrepresented bacteria. Since the total length of all genomes within the community may be similar to the length of a mammalian genome, metagenome assembly appears to be an extremely challenging problem not only regarding the quality of the resulting contigs, but in terms of computational resources required as well.

Assembly of eukaryotes

Eukaryotic genomes are known for their complex repeat structures, which complicate the problem of genome assembly by a margin. For example, the human genome contains various repeat families, such as ALUs (short 300 bp repeats with over a million copies in the genome), other short interspersed nuclear elements (SINEs), long interspersed nuclear elements (LINEs, typically about 7 kbp long), terminal repeats and various tandem repeats. To resolve such repeats eukaryotic genomes are assembled using a large variety of sequencing data: mate-pair libraries with different insert sizes, fosmid mate-pairs and genomic maps.

Genome Annotation

Assembled from short sequenced fragments genomic DNA contains all of the information about the metabolism of the organism, its development and responses to external stimuli. Most of these functions are carried out by proteins encoded within the genomic sequence. This means that the primary goal of any genome analysis is to identify protein encoding genes, determine their functions and then define and characterize the sections of DNA that regulate the amounts of these proteins being synthesized based on an exact point in time and conditions. This process is called *genome annotation*. At the start of the annotation process all possible start and end codons that delimit the parameters of protein encoding genes are identified. This stage is called *ORF calling* and will be described in more detail in the “Markov models and gene prediction” section.

It is important to keep in mind that ORF calling methods used for bacterial genomes cannot be applied to eukaryotic genomes, since the latter contain both coding (exons) and non-coding regions (introns). Introns are also significantly longer than exons (e.g., exons take up about 2% of the entire length of the human genome). Information, such as the frequency of encountering particular amino acids and synonymous codons and the knowledge of the length of the exons and introns is used in combination with other statistical data to identify genes in eukaryotic genomes. Despite the fact that genome annotation using statistical identification rules yields only very approximate data, it is still of great value as part of the whole process.

The best way to tackle this task is to compare the sequences of several different, but related genomes. Since exons and introns evolve with different speed (exons, evolve comparatively slower than non-coding segments, aka introns), we can use this information to highlight similar regions by comparing genome sequences to each other and as such, identify the overall location of the exons. The delimitations of these coding regions are then further refined via statistical methods.

Comparative analysis is also of help when trying to predict the function of the particular proteins encoded by the genes. If the level of similarity between the new protein and a previously researched and well described one (studied in a laboratory setting) is high, they can be considered as similar and are likely to have identical functions. The lower the degree of similarity between proteins, the more different their functions will be. To make sure that two protein coding genes from two different genomes are in fact the same gene, we must make sure that neither of these genes has a closer relative in a different genome. This stands true even if the function of these proteins is extremely similar. The quality and accuracy of such analysis is directly dependent on the availability of a large amount of high quality whole genome assembly reference data.

High quality predictions of protein functions play a crucial role in a large number of theoretical and experimental studies, such as for example research aiming to gain a deeper understanding of the underlying biochemical conditions related to numerous genetic diseases.

Not all genes in a genome encode proteins. Thus, instead of synthesizing protein, non-coding RNA genes are responsible for the production of functional RNA products. Non-coding RNA genes can be predicted by using various programs tRNAscan-SE (Lowe and Eddy, 1997), RNAMmer (Lagesen *et al.*, 2007) and BLAST (Altschul *et al.*, 1990) and data sources, as well as performing homology-based searches in such databases as Rfam (Burge *et al.*, 2013), the plant snoRNA database (Brown *et al.*, 2003) (for plant genomes), GenBank (Benson *et al.*, 2004) and ASRG (Wang and Brendel, 2004). RNA sequencing reads (if available) can be further mapped against the appropriate databases to strengthen the generated predictions.

The comparative sequence analysis approach coupled with functional genomics experiments allows annotating non-protein coding genomic regions.

A number of comprehensive annotation systems are available for carrying out functional annotation (see Further reading) for the interested reader to consider and use.

Markov models and gene prediction

Knowledge of the intrinsic gene structure is the main mechanism used in gene prediction. Indeed, the majority of genes have ATG (methionine) as a starting codon, though sometimes GTG and TTG are used as alternative starting codons. Certainly, there may be multiple ATG, GTG, or TGT codons in a frame, which means that the presence of these codons at the beginning of the frame does not necessarily give a proper indication of the translation initiation site. Therefore, another type of DNA structure, also associated with the translation initiation event, has to be used in addition to nucleotide content. One of such features is the ribosomal binding site (RBS) located upstream of the translation start codon. Knowing the ribosome binding site can help to determine the start codon. Each protein coding region ends in a stop codon that causes translation to stop. There are three possible stop codons, namely, TAG, TAA, and TGA, and all three of them are fairly easy to identify.

Manual prokaryotic gene identification relies on brute-force determination of ORFs and major features related to prokaryotic genes. As a part of this approach the DNA is first translated in all six possible frames (three frames on one strand and three frames on the opposite strand). It is worth mentioning that in a noncoding region a stop codon occurs on average every twenty codons, which means that a frame longer than thirty codons without any stop codons could be considered as putative gene coding region. The putative frame is further manually confirmed by the presence of other features such as a start codon and the RBS sequence.

Markov models can be very helpful in providing a probabilistic description of a gene sequence. A *Markov model* describes the probability distribution of nucleotides in a DNA sequence, where the conditional probability of a nucleotide occurring in a particular sequence position depends only on the nucleotides at k previous positions. The value k is called the *order* of a Markov model. This means that a zero-order Markov model implies that each of the bases occur independently with a given probability. This is a typical situation for noncoding parts of a genome. A first-order Markov model (or *Markov chain*) stipulates that the probability of the occurrence of a particular base will depend only on the base preceding it. A second-order model looks at the preceding two bases to determine the probability of occurrence of the following base. This model is a better fit for the codons in a coding sequence.

The use of the Markov models in gene finding exploits the idea that oligonucleotide distributions in the coding regions are different from those for the noncoding regions. Indeed, having the Markov models that describes the structure of coding and non-coding regions (these can be represented with Markov models of different orders) we can calculate the probabilities of occurrence of a particular sequence under these models. Comparing these probabilities or, better yet, calculating the likelihood ratio we could decide whether the particular sequence is a part of a coding region, or not. Since a fixed-order Markov model describes the probability of a particular nucleotide that depends on previous k nucleotides, the longer the nucleotide sequence, the more accurately the internal structure can be described for the coding region. Therefore, the higher the order of a Markov model, the better it can predict genes.

A protein-encoding gene is formed by nucleotides organized in triplets as codons, hence the more effective Markov models are constructed from the sets of three nucleotides, explaining the observed distributions of trimers or hexamers, and so on. The parameters of a Markov model have to be trained using a set of sequences with known gene locations. Once the parameters of the model are established, the model can be used to estimate the probabilities of trimers or hexamers in a new sequence.

Under normal circumstances the pairs of codons tend to correlate, and as a result, the frequency of a particular six nucleotides appearing together in a coding region can be much higher than occurring by random chance. As a result, a fifth-order Markov model, which calculates the probability of hexamer bases, can detect nucleotide correlations typical for coding regions more accurately and is in fact most often used (Wang *et al.*, 2004).

A potential problem of using a high-order Markov chain is that if there are not enough hexamers, which happens in short gene sequences, the method's efficacy might be limited. One way to deal with this limitation is a variable-length Markov model also known as the *interpolated Markov model* (IMM). The IMM samples the largest number of sequence patterns with Markov model orders (k) ranging from 1 to 8 and uses a weighting scheme, placing less weight on rare k -mers (outlining the worse accuracy of corresponding probability estimation) and more weight on more frequent k -mers. The probability produced by the final model is the sum of probabilities of all weighted k -mers. In other words, this method has more flexibility in using Markov models depending on the amount of data available. Higher-order models are used when there is an abundant amount of data and lower-order models are used when the amount of data is smaller (Salzberg *et al.*, 1998).

Surprisingly, the gene content and length distribution of prokaryotic genes can vary a lot. The majority of genes are in the 100–500 amino acids range with a nucleotide distribution derived from the GC content of the organism. However, there are atypical genes that are shorter or longer and have a variety of nucleotide frequency profiles. These genes tend to escape detection using the gene models trained on the typical data. Moreover, the models trained on the whole spectrum of the genes tend to produce worse results due to reduced precision. Ideally, to describe all genes in a genome fully more than one Markov model is needed. The standard way to combine different Markov models (that would represent typical and atypical nucleotide distributions) is via *Hidden Markov Models* (HMM).

A HMM combines two or more Markov models within only one consisting of observed states and others representing unobserved (or “hidden”) states that influence the outcome of the observed states (such unobserved state could be, for example, the type of the gene, or a particular part in the gene the nucleotide composition of which would differ from the other parts). In an HMM, as in a Markov model, the probability of going from one state to another state is the transition probability. Each state may be composed of a number of elements. For nucleotide sequences, there are four possible symbols, namely A, T, G, and C in each state. For amino acid sequences, there are twenty possible symbols. The probability value associated with the occurrence of each of the symbols in each state is called the emission probability. To calculate the total probability of a particular path of the model, both transition and emission probabilities linking all the “hidden” as well as observed states need to be taken into account.

The most popular prokaryotic gene prediction/ORF calling software are: Glimmer is based on interpolated Markov models (Salzberg *et al.*, 1998). GeneMark (Lukashin and Borodovsky, 1998) uses inhomogeneous three-periodic Markov chain models of protein-coding DNA sequences and could be viewed as an approximation of an HMM approach (Azad and Borodovsky, 2004).

Analyzing Transcriptomic Sequences

Quality Control of RNA-Seq

Initial quality control of RNA-Seq data can be performed using the same FastQC tool (Andrews, 2010), as used for genomic data. However, the FastQC reports for RNA-Seq data should be interpreted somewhat differently, compared to the genomic data. The main differentiating criteria for RNA-Seq data is the uneven coverage depth and the presence of ribosomal RNA sequences. Due to their high abundance, rRNA reads may introduce additional peaks into the GC content plot (Fig. 13), as well as create non-uniform k -mer content (Fig. 14).

The presence of unwanted rRNA reads is a typical problem for RNA-Seq experiments. Some sequencing protocols aim to filter out rRNAs during sample preparation, but such approach, however, may only remove a fraction of the rRNA reads from the dataset. Reads from rRNAs can be removed as contamination using, for example, the bbdut script from the bbtools package (see Section “Sequencing Data Formats” for the details), with known rRNA sequences provided as the database.

Aligning RNA Sequences

While alignment of prokaryotic RNA sequences to the reference genome can be performed with the same algorithms and methods used for DNA sequence alignment, the process of mapping eukaryotic RNA differs significantly due to the presence of splicing events. To support long insertions and skip intronic sequences splicing alignment algorithms are required. The most popular software tools for RNA to DNA mapping are BLAT (Kent, 2002), GMAP (Wu and Watanabe, 2005) and Splign (Kapustin *et al.*, 2008).

The problem of mapping eukaryotic RNA-Seq reads to the reference genome is further exacerbated by their short length and the presence of sequencing errors. One of the first tools for mapping RNA-Seq reads – TopHat – was based on the Bowtie aligner for genomic reads (Trapnell *et al.*, 2009). Later, STAR (Dobin *et al.*, 2013) and Hisat (Kim *et al.*, 2015) aligners were developed specifically to address the problem of rapid and accurate mapping of RNA-Seq data. All listed tools can take the gene database in

Fig. 13 GC content plot for normal Illumina RNA-Seq reads.

GFF format as input in addition to the reference genome, which increases the accuracy of the alignments and is especially true in the case of reads containing the splice junctions.

Mapping RNA-Seq reads can be of use as an additional reference based quality control. For example, the qualimap ([Okonechnikov et al., 2015](#)) tool calculates such statistics as fractions of exonic, intronic and intergenic reads, gene coverage profile and splice junction distribution. The RSeQC ([Wang et al., 2012](#)) can also be used as an alternative tool. In addition to the statistics listed above, it is capable of determining the insert size for paired-end RNA-Seq reads, estimate mismatch content and detect whether RNA-Seq data is *strand-specific* or not. In strand-specific RNA-Seq experiment the reads are sequenced either from the same or from the opposite strand of the gene that produces the RNA, which then allows to detect actual gene strand. RNA-Seq alignment can also be used to detect fusion genes – chimeric genes that can appear during genomic rearrangements in cancer cells ([Kim and Salzberg, 2011](#)).

Gene Counting and Differential Expression

The main application of RNA-Seq is the estimation of gene expression levels and *differential expression analysis* between multiple samples. Differential expression analysis implies the comparison of expression levels of the same genes/isoforms between samples under different conditions, such as cells under different treatments, healthy and ill patients, patients before and after medical treatment. The number of samples analyzed is the key to a successful analysis as only a correct choice will fully take advantage of RNA-Seq possibilities. To perform the differential expression analysis, a study requires at least three biological samples for each condition analyzed. This is because, when comparing gene expression between the different conditions, sample specific differences may affect the analysis and thus lead to inadequate conclusions, since these differences may not be related to the subject of research. Having an appropriate number of samples for each condition will reduce the impact of sample specific variability on the analysis. Both biological and technical variabilities within the samples can be reduced by normalization. The number of samples analyzed is also essential for the statistical tests required by any differential expression analysis. Most of them need at least three or more samples per condition to provide a statistically sound result. Less samples will suffice only for obtaining exploratory results, while more samples will increase the power of the analysis.

Fig. 14 k-mer distribution for normal Illumina RNA-Seq reads.

Since the isoforms of a gene contain the same exons, assigning each read to a specific isoform is much more complicated task than assigning those reads to the corresponding gene. Therefore, most RNA-Seq pipelines focus on gene level analysis, consisting of several steps.

Firstly, RNA-Seq reads are mapped to the reference genome ignoring reads that map equally well to more than one genomic location (multi-mappers) and assigned to the genes from the database. Afterwards, the number of reads assigned to each gene are counted, e.g., using `htseq-count` (Anders *et al.*, 2015). Some tools also allow to perform quantification without actually mapping the reads to the reference genome (Bray *et al.*, 2016). The gene counts can be normalized, usually by sequencing depth and gene length. The normalized counts are used to estimate relative change of the expression levels between different samples with a statistical test, e.g., a t-test or a test created specifically for RNA-Seq data. State-of-the-art software tools such as DESeq2 (Love *et al.*, 2014) and edgeR (Robinson *et al.*, 2010) require unnormalized raw counts and perform themselves the normalization step.

The results of the differential analysis are typically represented as a table with genes as rows and several values for each gene. Among these numbers, the most important are the measure of the change in gene expression between the conditions (usually a log fold-change) and the result of the statistical test, usually an *adjusted p-value*. Since thousands of tests are made, the adjusted p-value indicates the significance of the difference in expression (p-values are calculated for null-hypotheses stating that the expression level is the same for all conditions). The decision for calling a gene differentially expressed is not straightforward: it depends on arbitrary threshold values for both log fold-change (how much the expression has to change) and adjusted p-value (how many false positives can be tolerated).

Another way of exploring differential expression analysis results is using a heat map (see example in Fig. 15). Table rows correspond to the genes being examined, and each column corresponds to a single sample. Cells color represents estimated genes expression levels. The table is usually sorted according to the change in expression level between different conditions.

One of the possible biases that can significantly affect the results of differential expression analysis is the so called batch effect. The batch effect takes place when the difference between samples is caused by sample preparation or sequencing protocols, flowcell inconsistencies, variations between sequencer runs (Dündar *et al.*, 2015). These factors may lead to inappropriate calculation of expression levels and therefore, misleading interpretation of the results. *In silico* removal of the batch effect is implemented in various differential expression analysis toolkits, e.g., Deseq2 (Love *et al.*, 2014).

Fig. 15 An example of gene expression heat map for 6 samples under 2 different conditions and 22 genes.

De Novo Transcriptome Assembly

The *de novo* transcriptome assembly may appear to be a simpler problem than genome assembly due to the absence of long complex repeats and a smaller transcriptome total length. However, uneven coverage depth caused by varying expression levels, presence of isoforms from the same gene and paralogous genes complicate the process of transcriptome assembly. Most of the modern *de novo* transcriptome assembly tools, such as Trans-ABYSS (Robertson *et al.*, 2010) and SOAPdenovo-Trans (Xie *et al.*, 2014), are based on the existing de Bruijn graph genome assemblers. Trinity is the only assembler that was initially developed as stand-alone RNA-Seq assembler (Grabherr *et al.*, 2011).

As metagenomic studies became more popular, metatranscriptomics sequencing experiments have also become more frequent. Sequencing RNA of the bacterial community helps gain an understanding of its functionality. In some studies the usage of metatranscriptomic data is limited to the estimation of expression levels for known genes and tracking the signal pathways in the community under different conditions. In some projects, however, the *de novo* metatranscriptome assembly is also performed, although only a few tools are available now (Leung *et al.*, 2015; Ye and Tang, 2015).

Since the result of the *de novo* transcriptome assembly is completely different from the genomic contigs, other methods for quality evaluation are also needed. However, the same three distinct approaches can be applied for the assessment of assembled transcripts: Reference-based, based on gene content and *de novo*.

Reference-based approach includes alignment of the transcripts either to the reference genome with a known gene database via a spliced alignment method or to the isoform sequences themselves. The resulting alignments can be used to compute various statistics and metrics, such as *misassembled* transcripts, number of assembled genes and isoforms, duplication ratio along with mismatch and indel error rate. Recently developed rnaQUAST (Bushmanova *et al.*, 2016) and Transrate (Smith-Unna *et al.*, 2016) tools are designed specifically for the reference-based quality evaluation of *de novo* transcriptome assemblies.

Similar to the genome assemblies, the gene content can be estimated using BUSCO (Simão *et al.*, 2015), which allows to search for single-copy orthologs that are universal for the specific group of organisms. *De novo* gene identification can be performed with a modified version of a popular tool GeneMark, called GeneMarkS-T (Tang *et al.*, 2015). *De novo* quality evaluation based on raw reads for RNA-Seq assemblies is implemented in such tools as Transrate (Smith-Unna *et al.*, 2016) and Detonate (Li *et al.*, 2014).

Protein Data Analysis

All living cells contain proteins that are of a great importance for all biological objects. The structure of proteins is very complex and includes several levels of organization. The primary structure of a protein is usually represented as a string of amino acids starting from the amino-terminal (N-terminal) to the carboxyl-terminal (C-terminal) of the protein. It can be obtained as a result of the direct sequencing of the protein or deduced from the corresponding DNA or mRNA, since the order of bases on a DNA strand specifies the order in which the amino acids are linked together during translation. The amino acid sequence of proteins or peptides is basic information to understand proteins or peptides and predict its post-translational modifications and functions.

Protein Sequencing Technologies

The process of determination of the amino acid sequence is known as protein sequencing. Amino acids may be represented by a single- or three-letter codes. It is worth to mention that sequencing methods were originally developed specifically with proteins in mind, since people thought that proteins were the main genetic material. Researchers believed that the structure of DNA was too simple (composed of only four nucleotides) to play this role comparing to proteins, that can be built of 20 different amino-acids and thus have a higher heterogeneity as molecules. All protein sequencing methods can be divided into two groups: one group provides N-terminus sequence of a protein, while the second group of methods is used to sequence and identify the entirety of the protein. A label-cleavage method for protein sequencing was developed by Pehr Edman in 1950s (Edman *et al.*, 1950).

Edman degradation procedure (Fig. 16) is based on a three-stage reaction that labels and removes the N-terminal residue of a polypeptide, which can then be identified as a phenylthiohydantoin (PTH – Edman reagent) derivative.

Phenyl isothiocyanate, $C_6H_5N=C=S$, is a reagent that permits the progressive removal and identification of the N-terminal amino acid, leaving the rest of the chain unaffected. The truncated peptide after the first degradation has a new N-terminal amino acid that can again react with phenyl isothiocyanate and thus makes progressive removal of the subsequent amino acids possible. This technique cannot be applied if the N-terminus is modified. Removed amino-acid residues are then identified by chromatography (Berg *et al.*, 2002).

Edman sequencing is automated (Niall, 1973) and uses a protein sequenator that allows sequencing peptides of about 5–50 amino acids long. Polypeptides longer than 50–70 amino acids must be cleaved into smaller peptides before sequencing. Use of multiple endopeptidases for the same protein to break up long peptides allows obtaining overlapping fragments of peptide that can be used to produce final sequence. To be sequenced the peptide is adsorbed onto a solid surface.

Edman approach is known for impurities that commonly occur in the first round of degradation. Despite this fact, it remains a valuable tool for characterizing a protein's N-terminus and is still the most reliable, and accurate protein and peptide sequencing method that provides an unambiguous sequence read and is widely used for quality control purposes.

Another method for peptide end-group analysis was developed by Fred Sanger (Ryle *et al.*, 1955) who was awarded the 1958 Nobel Prize for Chemistry for sequencing insulin that was performed with the developed approach. Sanger method uses chemical derivatives to selectively label the N-terminus of a protein with the yellow dye fluorodinitrobenzene, followed by hydrolysis, and electrophoretic or chromatographic separation of the labeled N-terminal amino acid residue. Multiple rounds of partial protein hydrolysis, fractionation, and terminal amino acid determination lead to complete sequence of a protein. There is no robust method to sequence a protein or peptide from its C-terminus because carboxypeptidases – enzymes that are used as part of these methods – can remove only specific individual C-terminal amino acids (Bergman *et al.*, 2003).

Reconstructing Proteins From Mass-Spectra

Mass spectrometry (MS) methods are now the most widely used for protein sequencing and identification. Mass spectrometry is an analytical method that measures mass-to-charge ratio for ions in gas phase. MS breaks up peptides into individual amino acids using electric current, collects the released amino acids in mass spectrometer detector to be individually identified by their unique mass. The development of MS technology allowed to sequence the entire set of proteins of a living organism and thus became the trigger for the emergence of proteomics. (Tran *et al.*, 2017).

There are currently two major types of MS approaches to protein sequencing (Fig. 17): the *bottom-up* approach for the analysis of peptide mixtures from digested proteins and *top-down* mass spectrometry that is used to analyze intact proteins.

The bottom-up approach starts from the proteolytic digestion of proteins that creates complex peptide samples, which are then used in combination with high-throughput liquid chromatography (LC) and tandem MS* (LC-MS/MS; LC-MALDI MS/MS,

Fig. 16 Edman degradation procedure.

Fig. 17 MS approaches to protein sequencing.

Fig. 18 Theoretical and experimental spectra for the peptide sequence.

MALDI TOF/TOF) to enable large-scale protein characterization in proteomics (Fernández-Puente *et al.*, 2014). This approach should not be applied for small proteins, as they have less cleavage sites, which will lead to an insufficient amount of peptides.

The top-down MS uses liquid chromatography or 2-D gel electrophoresis to separate intact proteins from complex samples. This approach is successfully used to characterize the structures of large proteins and to detect post-translational modifications (Aken *et al.*, 2016).

To analyze an experimental MS spectrum it needs to be compared with theoretical spectra for each of the peptides in a database (see “Relevant Websites” section). Theoretical peptides with the best fit help reconstruct the sequence of the experimental peptide (Fig. 18). Numerous post-translational modifications of proteins make them hard to be identified in databases and create a challenging computational problem.

The main goal of peptide sequencing is to reconstruct the amino acid sequence of a peptide. This goal can be achieved by using data of MS/MS spectrum and the peptide mass. Each tandem mass spectrum covers only a short part of the protein and to reconstruct the primary structure one has to assemble tandem mass spectra of overlapping peptides generated from multiple proteolytic digestions of the protein. Sounds like a DNA assembly task. Doesn't it? Here too we are trying to reconstruct a long sequence from many small fragments. In the case of protein assembly this approach is called top-down MS. To continue the analogy with genomic assembly, we should mention that top-down tandem mass spectra rarely provide full coverage of a protein. Bottom-up tandem mass spectra are used to increase sequence coverage (Liu *et al.*, 2014).

Experiments using MS technologies produce huge amount of very complex data and require specialised software for their analysis (for example: PepNovo, PEAKS, NovoHMM, MSNovo, pNovo, UniNovo, Novor and DeepNovo (Tran *et al.*, 2017)). Noisy and ambiguous MS/MS spectra cause additional computational challenges and require improved algorithms.

To find out more about the current tools that help retrieve long sequence fragments of the target proteins from sets of bottom-up and top-down MS/MS spectra see publications in further readings.

Mapping Proteins to Genome

Proteomics is a science that studies the protein composition of biological objects, as well as the modifications and the structural and functional properties of proteins. The uniqueness of the mass spectrometry pictures of products produced by proteolytic protein hydrolysis for each protein is used to analyze them against theoretical mass spectrum collected in databases.

One of the main goals when studying protein is to match the protein to the gene its coding. Knowledge of the mass of the whole protein does not provide reliable information due to the insufficient accuracy of the measurement or the presence of modifications. Therefore, researches use a mass spectrometry peptide map of a protein that consists of mass values of peptides obtained as a result of highly specific hydrolysis (chemical or enzymatic) of a protein. Such sets are called "MS-peptide fingerprints".

The main approach of protein identification by mass-spectrometry is to compare the real, experimentally obtained mass spectrum with the theoretical ones from the database that correspond to the known proteins.

Existing algorithms and corresponding programs that allow the identification of proteins by their mass spectra can be divided into three main groups:

1. Programs using the protein proteolytic peptide fingerprint (MASCOT (Perkins *et al.*, 1999). ProFound (Zhang and Chait, 2000)),
2. Programs that work with the peptide fingerprint and MS/MS spectra (MASCOT, MS-Fit (see "Relevant Websites" section),
3. Programs that work with the MS/MS spectra only (SEQUEST (see "Relevant Websites" section), PepFrag (see "Relevant Websites" section), MS-Tag (see "Relevant Websites" section), Sherpa (Taylor *et al.*, 1996).

All programs mentioned above use publicly available databases of amino acid sequences of proteins or nucleotide sequences of genes. Some of the most popular programs that contain protein sequences are: UniProt, a powerful database of annotated proteins (see "Relevant Websites" section); UniProtKB (see "Relevant Websites" section), a database that consists of Swiss-Prot (a collection of manually annotated and curated sequences) and TrEMBL (automatically annotated protein sequences translated from the nucleic acid sequences stored in EMBL) (Bairoch and Apweiler, 2000); UniRef, which contains sequence clusters for fast sequence similarity searches (see "Relevant Websites" section) and UniParc, a sequence archive of sequences and their identifiers (see "Relevant Websites" section); Protein Sequence Database (PSD) in the Protein Identification Resource (PIR, Barker *et al.*, 1999), containing annotated protein sequences; NCBI nr protein database, including entries from the non-redundant GenBank translations (see "Relevant Websites" section), UniProt, PIR (Barker *et al.*, 1999), Protein Research Foundation (PRF) in Japan (see "Relevant Websites" section), and the Protein Data Bank (PDB, see "Relevant Websites" section). Only entries with absolutely identical sequences are merged (Xu, 2004). Most of these databases also provide a sequence search tools.

Protein-Protein Alignment

Pairwise sequence alignment is a fundamental component of many bioinformatics problems. It is extremely useful in structural, functional, and evolutionary analyses of sequences since it provides information about the level of similarity between two sequences.

The overall goal of pairwise sequence alignment is to find the best "pairing" of two sequences of DNA, RNA, or protein, maximizing the number of similar characters. To achieve this, one sequence needs to be spread relative to the other to find the positions where maximal correspondence can be found. There are two main alignment strategies that are most often used: global alignment and local alignment.

In *global alignment*, the two sequences to be aligned are assumed to be generally similar over the entirety of their length. Alignment is carried out from the start and till the end of both sequences to find the best possible alignment across the entire length between the two sequences. This method is more applicable for aligning two closely related sequences of (roughly) the same length. Note that this method is not suitable for identifying the highly similar local regions between the two sequences.

Local alignment, on the other hand, does not assume that the two sequences in question are similar over their entire length. In fact, it only determines regions with the highest level of similarity between the two sequences and aligns only these regions without taking into account the alignment of the rest of the sequences. This approach can be used for aligning more divergent sequences with the goal of searching for conserved patterns in DNA or protein sequences.

The way the alignment algorithms (both global and local) are implemented is fundamentally similar, with the exception of the optimization strategy used in aligning similar residues. Typically the alignment is performed by means of *dynamic programming*.

Dynamic programming is a method that determines the optimal alignment by matching two sequences against each other to identify for all possible pairs of matching characters between them. During this process a two-dimensional matrix is created and the two sequences to be compared are both laid out of the two axes. The symbols are then matched in according to the particular *scoring matrix*. Alignment scores are calculated one row at a time. The process starts with the first row of one sequence, which is used to scan through the entire length of the other sequence. The matching scores are calculated. The scanning of the second row takes into account the scores previously obtained during the first round. The best score is put into the bottom right corner of an intermediate matrix. This process is iterated until values for all the cells are filled. The scores are thus accumulated along a diagonal going from the upper left corner to the lower right corner. Once the matrix with the scores has been computed, the next step is to find the path that represents the optimal alignment. This is done by tracing back through the matrix in reverse order from the lower right-hand corner toward the origin of the matrix in the upper left-hand corner. The best matching path is the one that has the maximum total score. If two or more paths reach the same highest score, one is chosen arbitrarily to represent the best alignment. The path can also move horizontally or vertically at a certain point, which corresponds to the introduction of a gap or an insertion or deletion for one of the two sequences.

Gap penalties

Alignment between sequences often involves adding *gaps* that represent insertions and deletions. Note that special care should be taken when allowing gaps within the scoring scheme: if the gap penalty values are set too low, the gaps can become too numerous to allow even non-related sequences to be matched up with high similarity scores. If the penalty values are set too high, gaps may become too difficult to appear, which would stand in the way of the creation of a reasonable alignment.

Another factor to consider is the cost difference between opening a gap and extending an existing gap. Normally a gap opening should have a much higher penalty than a gap extension. This is based on the rationale that if insertions and deletions ever occur, several adjacent residues are likely to have been inserted or deleted together. These differential gap penalties are also referred to as *affine gap penalties*. Under normal circumstances separate gap penalty values are assigned for introducing and extending gaps. For example, one may use a $-12/-1$ scheme, in which the gap opening penalty is equal to -12 and the gap extension penalty is given the value of -1 . The total gap penalty W is a linear function of gap length, which is calculated as $W = \gamma + \delta \times (l-1)$, where γ is the gap opening penalty, δ is the gap extension penalty, and l is the length of the gap (Gotoh, 1982). Besides the affine gap penalty, a constant gap penalty is sometimes also used, which assigns the same score for each gap position regardless whether it is an opening or an extension. In addition to that, end gaps can be allowed to be free (their inclusion will have zero penalty) to avoid getting unrealistic alignments.

Dynamic programming for global alignment

The classical global pairwise alignment algorithm using dynamic programming is known as the Needleman – Wunsch algorithm (Needleman and Wunsch, 1970). The aim this algorithm is to identify the optimal alignment is obtained over the entire lengths of the two sequences. It must extend from the beginning to the end of both sequences to achieve the highest total score. In other words, the alignment path has to go from the bottom right corner of the matrix to the top left corner. The possible drawback of focusing on trying to get a maximal score for the full-length sequence alignment is the risk of missing the best local similarities, which means that this strategy is only suitable for aligning two closely related sequences that are of the same length.

Dynamic programming for local alignment

In a regular sequence alignment, the level of divergence between the two sequences is not known in advance. The lengths of the two sequences may also differ. In cases such as these, it is of more value to identify the regional similarities between the two sequences than to try finding a match that would include all of the symbols. The dynamic programming approach to local alignment is known as Smith – Waterman algorithm (Smith and Waterman, 1981). In this algorithm, positive scores are assigned to matching symbols and zeros to mismatches. No negative scores are used. Occasionally, several optimally aligned segments with best scores are obtained. As in the global alignment, the final result is influenced by the choice of the scoring systems used. The goal of a local alignment is to get the highest alignment score locally, which may be at the expense of the highest possible overall score for a full-length alignment. This approach may be suitable for aligning divergent sequences or sequences with multiple domains that may be of different origins.

Scoring matrices

In the dynamic programming approach the alignment procedure has to make use of a scoring system, which represents a set of values used for the purpose of quantifying the likelihood of one symbol being substituted by another in an alignment. The scoring system is called a *substitution matrix* and is derived from the statistical analysis of symbol substitution data from sets of reliable alignments of highly related sequences. Scoring matrices for nucleotide sequences are relatively simple: a positive value or high score is given for a match and a negative value or low score for a mismatch. This assignment is based on the assumption that the frequencies of mutation are equal for all bases. However, this assumption may not be realistic; typically transitions (substitutions between purines and purines or between pyrimidines and pyrimidines) occur more frequently than transversions (substitutions

between purines and pyrimidines). Therefore, a more sophisticated statistical model with different probability values to reflect the two types of mutations is needed.

Scoring matrices for amino acids are much more complicated because the scoring systems have to reflect both the properties of amino acid residues, as well as the likelihood of certain residues being substituted among the homologous sequences. Certain amino acids with similar chemical properties can be more easily substituted than those having vastly different characteristics. Substitutions among similar residues are likely to preserve the essential functional and structural features. Substitutions between residues of different chemical properties, however, are more likely to cause changes (and even disruptions) to the structure and function. Such type of substitution is less likely to be favored by evolution since it is more likely to yield nonfunctional proteins.

For example, phenylalanine, tyrosine, and tryptophan all share aromatic ring structures. Because of their chemical similarities, they can be easily substituted for one another without changing the regular function and structure of the protein. Similarly, arginine, lysine, and histidine are all large basic residues and there is a high probability of them being freely interchanged. The hydrophobic residue group includes methionine, isoleucine, leucine, and valine. Small and polar residues include serine, threonine, and cysteine. Residues within these groups have high a likelihoods of being substituted for each other. However, cysteine contains a sulfhydryl group that plays a role in metal binding, as well as active site, and disulfide bond formation. Substitution of cysteine with other residues therefore often reduces the enzymatic activity or destabilizes the protein structure. This residue is thus very rarely substituted. Small and nonpolar residues such as glycine and proline are also unique since their presence often disrupts regular protein secondary structures and therefore the substitutions with these residues do not frequently occur.

Amino acid scoring matrices

Amino acid substitution matrices are 20×20 and have been developed to reflect the likelihood of residue substitutions. There are two possible types of amino acid substitution matrices: one type is based on the interchangeability of the genetic code or amino acid properties, and the other is derived from empirical studies of amino acid substitutions. Although the two different approaches have a certain degree of overlap, surprisingly, the first approach, based on the genetic code or the chemical features of amino acids, has been shown to be less accurate than the second approach, which is based on the comparison of actual amino acid substitutions among related proteins.

The empirical amino acid scoring matrices, which include PAM (Dayhoff *et al.*, 1978) and BLOSUM (Henikoff and Henikoff, 1992) matrices, are derived from actual alignments of highly similar sequences. By analyzing the frequencies of amino acid substitutions in these alignments, a scoring system can be developed by giving a higher score to more likely substitutions and correspondingly lower scores for rare ones.

Statistical significance of a sequence alignment

Once a sequence alignment showing some degree of similarity is achieved, it is important to double check whether the observed sequence alignment is indeed sound or could have been occurred by pure chance. A truly statistically significant sequence alignment might be able to provide some results connected with the homology between the sequences being aligned.

To solve this problem one must make use of a procedure designed to assist with the estimation of the probabilistic distribution of the alignment scores of the two unrelated sequences of the same length. By calculating alignment scores of a large number of unrelated pairs of sequences, a distribution model of the randomized sequence scores can be derived. It turns out that the distribution in question is the so-called Gumbel distribution (or Generalized extreme value distribution of type I) for which a mathematical expression is available. This means that given a sequence similarity value the statistical significance can be accurately estimated (Altschul *et al.*, 1990).

Multiple sequence alignment

A natural extension of pairwise alignment is multiple sequence alignment, which aims to align multiple related sequences to achieve their optimal matching. Usually such related sequences are identified through a database similarity searching. As the process generates multiple matching sequence pairs, it is often necessary to somehow turn separate pairwise alignments into a single alignment, which arranges sequences in such a way that evolutionarily equivalent positions across all sequences are matched.

The multiple sequence alignment has the unique advantage of being able to reveal more biological information than many of the pairwise alignments. For example, it allows to identify conserved sequence patterns and motifs in the whole sequence family, which would not be easy to detect when comparing only two of the sequences. Many conserved and functionally critical amino acid residues can be identified in a protein multiple alignment. Multiple sequence alignment is also an essential prerequisite to carrying out phylogenetic analysis of sequence families and prediction of protein secondary and tertiary structures.

It is theoretically possible to use dynamic programming to align any number of sequences in the similar way as for pairwise alignment. However, it is worth keeping in mind that the amount of computing time and memory required will increase exponentially the more sequences are being compared. As a consequence, full dynamic programming usually cannot be applied for datasets of more than 10–25 sequences. In practice, heuristic approaches are most often used that provide sub-optimal, but still extremely useful solutions. There are different approaches that could be used to perform multiple sequence

alignment. For the sake of the simplicity we will describe only one, namely, the *progressive alignment* approach (Feng and Doolittle, 1996).

Progressive alignment depends on the stepwise assembly of multiple alignment and is heuristic in nature. It speeds up the alignment of multiple sequences through a multistep process. It first conducts pairwise alignments for each possible pair of sequences using the Needleman–Wunsch global alignment method and records these similarity scores from the pairwise comparisons. The scores can be, for example, a percent identity or similarity scores based on a particular substitution matrix. Both do correlate with the evolutionary distances between the sequences. The scores are then converted into evolutionary distances to generate a distance matrix for all the sequences involved. A simple phylogenetic analysis is then performed based on the distance matrix to group sequences based on pairwise distance scores. As a result, a phylogenetic tree is generated using the neighbor-joining method. The tree reflects the evolutionary proximity among all the sequences.

Despite the fact that the resulting tree will only be an approximation, it still can be used as a guide for directing realignment of the sequences. For that reason, it is often referred to as a *guide tree*. According to the guide tree, the two most closely related sequences are first re-aligned using the Needleman – Wunsch algorithm. To align additional sequences, the two already aligned sequences are converted to a consensus sequence with fixed gap positions. The consensus is then treated as a single sequence in the subsequent step. In the following step, the next closest sequence based on the guide tree is aligned with the consensus sequence using dynamic programming. More distant sequences or sequence profiles are subsequently added one at a time in accordance with their relative positions on the guide tree. After realignment with a new sequence using dynamic programming, a new consensus is derived, which is then used for the next round of alignment. The process is repeated until all the sequences are aligned.

See sections “Further readings” and “Software” for the list and details of software tools and web portals used in nucleotide and protein sequence alignment.

Metabolic Pathways Analysis

The functions of about half of the genes in a bacterium can be reliably insinuated by comparing them to reference databases. This approach allows to compile an overall approximation of the metabolic map of the organism, which describes the substances the bacterium is able to synthesize on its own, the substances it needs to absorb from its environment, what constitutes its source of energy etc. These maps can then be further refined and cleaned of any possible errors by adjusting the similarity and other criteria.

The results of these studies can be used in such fields as biotechnology, agronomy, pharmaceuticals and medicine. The analysis of the metabolic pathways of commercial strains helps optimize the release of the intended product of interest. For example, enzymes that trigger key reactions in pathogens can be used as potential targets for new types of antibiotics.

Metabolic Pathways

Series of interactions between molecules in a cell that lead to assembly of new molecules in a cell, turn genes on and off, maintain and control the flow of information, energy and biochemical compounds are called biological pathways.

The most common types of biological pathways are involved in the metabolism of a cell (metabolic pathways), gene expression regulation (genetic pathways) and signal transmission (signal transduction pathways).

Metabolism can be defined as a series of chemical transformations of matter and energy taken from the environment aimed to maintain an organism’s life. Metabolic pathways in their turn are a series of biochemical reactions that convert substrates into products.

Metabolism can be conditionally divided into two opposite streams of transformations: anabolism and catabolism.

Anabolism refers to all processes involved in the creation of new substances, cells and tissues in the body. Examples of anabolism include synthesis of proteins and hormones, creation of new cells, accumulation of fats, and creation of new muscle fibers. The sum of all processes in the body that lead to the creation of any new substances and tissues is called anabolism.

On the flip side we have catabolism, which encompasses the processes involved in splitting complex substances into simpler ones, as well as decay of old cell parts and tissues of the body. An example of catabolism is the breakdown of fats and carbohydrates to produce energy, which in turn can be used for the synthesis of the substances of use to the organism, the creation of cells and the overall renewal of the body. It follows that both anabolism and catabolism are very closely interrelated to each other. The most important metabolic pathways in humans are: glycolysis, citric acid cycle (Krebs’ cycle), oxidative phosphorylation, pentose phosphate pathway, urea cycle, fatty acid β -oxidation, gluconeogenesis.

The most convenient way to investigate metabolic pathways is by analyzing metabolic models. They contain all the information about the reactions that can occur in a cell, how the reactions are related to each other, the activity of which genes can regulate the reactions, which of the reactions relate to standard metabolic pathways, and which are the most important, how they are combined into metabolic pathways and how they interact with each other.

Regulation of metabolic pathways is achieved through complex interactions of a large number of factors. As a result of the proper functioning of all metabolic pathways, the cell can maintain a stable homeostasis and properly respond to changes in the external environment. The availability of a large volume of genomic information (assembled genomes) facilitates the study of metabolism regulation. Based on this information, whole genome metabolic models generalizing the available ideas about

metabolism and its regulation are constructed. Such models include a list of all possible reactions, a set of rules for the regulation of individual reactions, thermodynamic limitations that determine possible directions of reactions.

Methods of metabolic models analysis can be subdivided into two groups: qualitative (topological analysis, flux balance analysis, structural kinetic models) and quantitative (structural kinetic models, kinetic models) (Tomar and De, 2014). A number of methods also use information about the atomic structure of metabolites. They allow to analyze the transition from individual metabolites to biochemical reactions.

The development of bioinformatics methods to interpret data led to the development of metabolic pathway analysis methodologies, including structural and stoichiometric analysis, metabolic flux analysis, metabolic control analysis, and several kinetic modeling based analysis. The article written by Dr. Namrata Tomar and Dr. Rajat K. (Tomar and De, 2014), provides the comprehensive survey on the existing metabolic pathway analysis methodologies.

A review of the most common approaches for the construction of computational models of metabolic systems can be found in (Rice *et al.*, 2008).

Metabolic Databases

Metabolic models can be obtained from different sources.

The KEGG database contains a large amount of information on metabolic reactions. It includes several separate databases, such as: KEGG REACTION – with information on biochemical reactions; KEGG COMPOUND and KEGG GLYCAN – about metabolites; KEGG ENZYME – about enzymes; KEGG GENES – about the genes; KEGG PATHWAY and KEGG MODULES – about metabolic pathways.

This database was developed for bioinformatics analysis in genomics, metagenomics, metabolomics, modeling and simulation in systems biology, and translational research in drug development. It contains about 4000 organisms, including 123 animals. The database is curated and requires a paid license for full access. Some information is available for free via the web interface and the program interface (Kanehisa *et al.*, 2008, 2012, 2014, 2016, 2017). One can analyze new sequences (DNA or protein) against metadata stored in the KEGG database by mapping them to the known pathways, models, orthologs and so on (See “Relevant Websites” Section) by linking new genomes to well curated known pathways.

The BioCyc database is similar to the KEGG database. It contains about 7600 organism-specific bases. Some of them are manually curated, including the base containing human data. Another ones, including the mouse DB, are partially supervised.

The metabolic models are also stored in the EBI BioModels Database. This free to use DB contains about 2500 whole genome metabolic models in SBML format, but all of them are generated automatically from KEGG and MetaCyc databases.

The Reactome database is another free database with information on metabolic and molecular pathways. This carefully curated database focuses mainly on human biology. Data from the database can be downloaded in SBML and other formats.

There are several end to end data pipelines dedicated to help with the complex task of metabolic pathways analysis (Poskar *et al.*, 2014; Abubucker *et al.*, 2016).

Gene Ontology

Gene ontology (GO) is a major bioinformatics initiative to unify the representation of gene and gene product attributes across all species (see “Relevant Websites” section).

Because the complexity of biological systems and the sizes of the datasets that need to be analyzed continue to grow, biomedical research is becoming increasingly dependent on knowledge stored in computable form. The Gene Ontology (GO) project is a collaborative effort to address the need for consistent descriptions of gene functions and gene products across different databases. The GO knowledgebase is composed of three primary components:

1. *Gene Ontology*, which provides the logical structure of the biological functions (‘terms’). It is structured as a directed acyclic graph where each term has defined relationships to one or more other terms in the same domain and sometimes to other domains. The ontology includes data on: *cellular components*; *molecular functions* and *biological processes* (see “Relevant Websites” section).

Molecular function corresponds to activities that can be performed by the individual gene products or by the assembled complexes of gene products.

A biological process in GO is not the same as a pathway since GO does not include information about the dynamics or the dependencies, both of which would be required to fully describe a pathway.

The GO vocabulary is species-neutral, and includes terms applicable to prokaryotes and eukaryotes, single or multicellular organisms.

2. *GO annotations* are evidence-based statements relating a specific gene product (a protein, non-coding RNA, or macromolecular complex, which we referred as ‘genes’ for simplicity) to a specific ontology term.
3. *Tools* that facilitate the creation, maintenance and use of ontologies. Software being developed aims to help edit and perform logic based analysis of ontologies, provide web access to the ontology and its annotations, and analyze data using the information in the GO knowledgebase to support biomedical research.

Ontologies can be browsed using a range of web-based browsers (see “Relevant Websites” section).

The overall goal of GO is to create a comprehensive model of biological systems. Currently, the GO knowledgebase includes experimental findings from almost 140,000 published papers (see “Relevant Websites” section), represented by over 600,000 experimentally-supported GO annotations, on the basis of which an additional 6 million functional annotations for a diverse set of organisms spanning the tree of life can be inferred.

That said, it is worth mentioning that GO does not store gene sequences and is not a catalog of gene products. GO describes how gene products behave in a cellular/organism context. The use of GO terms by the collaborating databases provides controlled vocabularies that are structured to facilitate querying at different levels and also to allow annotators to assign properties to genes or gene products at different levels, depending on the depth of knowledge about the particular entity.

Conclusions

Due to the rapid evolution of new methodologies in molecular and computational biology evolve, the aim of this article was to only provide a general overview of sequence analysis at the DNA, RNA, and protein and metabolic pathways level.

We have attempted to briefly cover both the general approaches, and the most popular and powerful tools that are currently being used to analyze large amounts of data from labs around the world.

Biographical Sketch

Andrey Prijibelski (formal transliteration Przhevalsky) received BSc degree in informatics from St. Petersburg State Technical University in 2010 and MSc in applied mathematics and physics from St. Petersburg Academic University in 2012. In 2011 he started an internship at Algorithmic Biology Lab led by Prof. Pavel Pevzner in St. Petersburg Academic University and then continued to work there as a junior research fellow. In 2014 the whole laboratory moved to St. Petersburg University and became Center for Algorithmic Biotechnologies (CAB). Andrey participated in development of one of the main lab projects – SPAdes de novo genome assembler and in 2014 received outstanding student paper award at ISMB 2014, Boston. Later he participated developing SPAdes-based de novo transcriptome assembler and improving SPAdes for large genome assembly. Andrey also teaches “NGS data analysis” for master students St. Petersburg Academic University and participates in various bioinformatics workshops and schools as a teacher and co-organizer.

Anton Korobeynikov received the MSc and PhD degrees in applied mathematics from St. Petersburg State University, Russia, in 2007 and 2010, respectively. He started to work at St. Petersburg State University in 2007, where he currently holds the position of Associate Professor of Statistical Modeling Department, School of Mathematics and Mechanics. The main areas of research interests of Dr. Korobeynikov are computational and applied statistics, including time series analysis, efficient implementation of algorithms of computation statistics and probabilistic methods in bioinformatics.

In 2012 he joined Algorithmic Biology Laboratory at St. Petersburg Academic University. The laboratory led by Prof. P. Pevzner is developing SPAdes – a novel de novo assembler suitable for single cell and multi cell data among other tools. In 2014 the whole laboratory moved to St. Petersburg University and became Center for Algorithmic Biotechnologies. Currently Anton is a SPAdes team leader and oversees the technical questions related to SPAdes development.

Professor Alla Lapidus holds a PhD in Molecular Biology from the Institute for Genetics and Selection of Industrial Microorganisms (IGSIM) and an MS Degree in Physics from the Moscow Engineering Physics Institute. Her primary areas of expertise include high-throughput DNA sequencing, genome structure analysis, reference quality genome assembly, bioinformatics. Currently the deputy-director of the Center for Algorithmic Biotechnology, St. Petersburg State University, Dr. Lapidus was previously an Associate professor at Fox Chase Cancer Center. From 2003 Dr. Lapidus has been applying high-throughput DNA sequencing, genome-wide analysis and bioinformatics to the study of microbial and fungal genomes and metagenomic communities by optimizing data QC, data analysis and de-novo assemblies at Joint Genome Institute (JGI). She has spearheaded multiple projects using NGS to optimize data QC, analysis and de-novo assemblies, created microbial finishing pipeline from the ground up and was the mind behind the development of the next generation de-novo assembly algorithms.

Previously she served as the Director of Sequencing Center, Integrated Genomics, as a Senior Research Scientist at the INRA, France, at The University of Chicago and at the IGSIM, Moscow. Professor Lapidus has authored several on-line courses on Bioinformatics and is a lead of the MS program “Bioinformatics” at SPbU. She also authored and co-authored over 350 papers and patents.

Sequence Composition

Jin Xing Lim and Bryan T Li, Temasek Polytechnic, Singapore

Introduction

Since the sequencing of *Escherichia coli* (Moxon and Higgins, 1997) and *Plasmodium falciparum* (Cowman and Crabb, 2002) genome, DNA sequence has been commonly known as the “blueprint of life” as DNA is the hereditary molecule for cellular life. Hence, logically should contain all the information necessary to infer the activities of life even though such inference may not be obvious. Despite so, a lot of information about the regulation of a gene, as well as the function of the gene product may be derived from its sequence. For example, common response elements across multiple genes at the promoter region suggest induction by the same external stimulus (Domenech *et al.*, 2001). In this article, we will look at various DNA sequence features at the DNA and review several recent applications where sequence features are used. Through these applications, we can appreciate that sequence composition is an integral aspect of sequence analysis.

DNA Sequence Composition

In this section, we will look at 6 major DNA sequence composition features: promoter, enhancer, ribosome binding site, coding sequence, terminator, methylation sites and CpG islands.

Promoter is a short DNA region of 100–1000 base-pairs upstream of the coding sequence that triggers gene transcription. Hence, identifying the promoter indicates the start of transcriptional activity leading to the start of a potential mRNA molecule. A desktop tool capable of finding promoter is ProSOM (Abeel *et al.*, 2008). The core promoter has exclusive features that cannot be found in other sequences when comparing with the average structural profile based on based stacking energy of transcribed. The program that is used for ProSOM is able to distinctly differentiate between the structural profiles of promoter sequences and other genomic sequences. It is done based on unsupervised clustering of physical properties of DNA by using self-organising maps. Additional tests on the ENCODE regions of the human genome yield high precision, showing 98% of all predictions made by ProSOM can be associated with transcriptionally active regions (Abeel *et al.*, 2008). Another tool that we can use is CoreBoost_HM (Wang *et al.*, 2009). It is a web-based tool that is an upgraded version of CoreBoost (Zhao *et al.*, 2007), which predicts core-promoters by applying a boosting technique with stumps, using both the small-scale and large-scale DNA sequence features. CoreBoost_HM uses the same technique as CoreBoost but with the addition of histone modification features as well. CoreBoost_HM can be used to identify and characterise the core-promoters of both coding and noncoding genes with high sensitivity and specificity at high resolution (Wang *et al.*, 2009). ChromHMM (Ernst and Kellis, 2012) characterises chromatin states, it can facilitate the biological characterization of each state by automatically computing state enrichments for large-scale functional and annotation datasets (Ernst and Kellis, 2012). Hence, ChromHMM is also able to locate promoter.

Enhancer is a short DNA region of 50–1500 base-pairs that increases the chance of occurrence of a particular gene’s transcription through binding by a type of proteins called activators. One tool that can help us locate enhancers is ChromHMM (Ernst and Kellis, 2012). It is a desktop software that discovers and characterises chromatin states from multiple chromatin datasets through automation. Based on a multivariate Hidden Markov Model, ChromHMM accurately models the existence of each chromatin mark. As a result, it can then be used to annotate a genome in one or more cell types orderly; hence locating sequence features such as enhancers (Ernst and Kellis, 2012). Another tool that can locate enhancers is EnhancerPred (Jia and He, 2016). It is a web-based tool that differentiates between enhancers and non-enhancers and measures enhancer’s strength with overall accuracies of 77.39% and 68.19% respectively. From combination of bi-profile Bayes and pseudo-nucleotide composition, it presents as a binary classification problem and EnhancerPred solves it using a machine learning algorithm, which is a two-step rapper-based feature selection method (Jia and He, 2016).

Ribosome binding site (RBS) is a nucleotide sequence upstream of an mRNA transcript’s start codon, which engages a ribosome during protein translation’s initiation. One web-based tool we can use to locate RBS is the Ribosome Binding Site Calculator (Salis, 2011). It is a design method that predicts and controls bacteria’s translation initiation and protein expression. For each start codon in a mRNA transcript, the method can foresee the translation initiation’s rate. A targeted translation initiation rate of a synthetic RBS sequence can be achieved through optimization method. Through the RBS calculator, a protein coding sequence’s translation rate may be logically controlled across a 100,000 fold range (Salis, 2011; Salis *et al.*, 2009). Another desktop tool that we can use is Estimated Locations of Pattern Hits (ELPH; see “Relevant Websites sections”), which takes a set of DNA or protein sequences, up to thousands of sequences, as input and locates motifs using Gibbs sampling. The program seeks through the set of sequences for the most common motif, assuming that each sequence contains one copy of the motif. ELPH can also be used to find patterns such as RBSs and exon splicing enhancers (ESEs).

Coding sequence (CDS) of a gene is the portion of a gene’s DNA, which comprised of exons, that is used to code for protein. One web tool that we can use to find CDS is ORFfinder by NCBI (see “Relevant Websites sections”). An open reading frame (ORF)

is the portion of a DNA sequence, in continuous, non-overlapping triplets called codons, that has the potential to be translated to protein. By finding ORFs, it is equivalent of finding the potential CDSs of a gene. ORF finder is a graphical analysis tool which seeks for ORFs in your input DNA sequence. Other than returning the range of each ORF, it gives its protein translation as well. The predicted protein is verified using SMART BLAST or regular BLASTP. However, the web version of the ORF finder is limited to sequences up to 50 kb long. Another web tool that we can use is ORFPredictor (Min *et al.*, 2005). It is designed to locate protein-coding segments in expressed sequence tag (EST)-derived sequences. For query sequences with a hit in BLASTX, the program predicts the CDS based on the translation reading frames classified in BLASTX alignments. Otherwise, it predicts the most probable CDS based on the inherent signals of the query sequences. The output includes the predicted peptide sequences in the FASTA format and a definition line that consists of the query ID, the translation reading frame and the range of the CDS. However, the ORFPredictor web server is limited to data of file size up to 20 Mb. For datasets exceeding the limitations, there is a standalone desktop version available for download (Min *et al.*, 2005).

Transcription terminator is a DNA segment that indicates the end of a gene or operon during transcription. Together with the preceding promoter, they delimit the transcriptional boundaries. This segment produces signals in the newly synthesized mRNA that initiate processes which break the mRNA off from the transcriptional complex to intervene transcriptional termination. One web-based tool we can use to locate transcription terminal is ARNold (Naville *et al.*, 2011). Rho-independent termination is an important mechanism in bacteria that causes RNA transcription to terminate and release the newly transcribed RNA. ARNold is able to locate rho-independent terminators in DNA sequences. This search method incorporates two complementary prediction programs, Erpin and RNAmotif, and performs approximately as well as more complex methods while being available to the non-specialist. Erpin (Gautheret and Lambert, 2001) generates a lod-score profile and seeks high scoring instances of the profile in the user's sequence with a structure-annotated alignment of 1200 terminator sequences from *Bacillus subtilis* and *Escherichia coli* as training set. On the other hand, RNAmotif (Macke *et al.*, 2001) uses a descriptor developed by Lesnik *et al.* (2001) to recognise terminators. RNAmotif matches are scored using the sequence contents of T-rich region and stability of the stem loop region, with an empirical score cutoff is defined to accept or reject matches. The free energy of the predicted terminator stem-loop structure using RNAfold (Hofacker *et al.*, 1994) is generated to provide a uniform scoring scheme for Erpin and RNAmotif hits. Another way to locate transcription terminators is through WebGeSTer DB (Mitra *et al.*, 2011). It is one of the largest database of intrinsic transcription terminators. The database consists of a million terminators found from 1060 bacterial genome sequences and 798 plasmids. Both graphic and tabular results on putative terminators can be generated and are arranged in tiers to allow easy retrieval. An interactive map has been integrated to visualise the distribution of terminators across the whole genome (Mitra *et al.*, 2011).

DNA methylation happens when a methyl group is added to either one of the DNA's bases, cytosine or adenine. Methylation can modify the activity of a DNA region without changing the sequence. The process commonly is used to repress gene transcription when located in a gene promoter. Methylation is necessary for normal development and gene expression control such as genomic imprinting and X-chromosome inactivation (for males). One desktop tool that we can use is BS-Seeker2 (Guo *et al.*, 2013), an updated version of BS-Seeker (Chen *et al.*, 2010). It is used to map the bisulfite-treated reads and generate DNA methylomes – nucleic acids that undergo methylation modifications. Together with high-throughput sequencing, bisulfite treatment provides a useful approach for studying DNA methylation at base resolution across the genome. The use of libraries such as whole genome bisulfite sequencing (WGBS) and reduced represented bisulfite sequencing (RRBS) to generate DNA methylomes improves mappability, efficiency and accuracy of the reads. BS-Seeker2 also is equipped with additional function to filter out reads with incomplete bisulfite conversion. This will minimise the overestimation of DNA methylation levels (Guo *et al.*, 2013). Another desktop tool that we can use is MethGo (Liao *et al.*, 2015). Similar to BS-Seeker2, this software tool analyses bisulfite sequencing (BS-Seq) data from WGBS and RRBS and provides 9 analyses (both genomic and epigenomic) in 5 major modules to profile (epi) genome. The 9 analyses include coverage distribution of each cytosine, global cytosine methylation level, cytosine methylation level distribution, cytosine methylation level of genomic elements, chromosome-wide cytosine methylation level distribution, gene-centric cytosine methylation level, cytosine methylation levels at transcription factor binding sites (TFBSs), single nucleotide polymorphism (SNP) calling and copy number variation (CNV) calling (Liao *et al.*, 2015).

Besides adenine, cytosine can also be methylated. CpG islands are segments of DNA where a cytosine nucleotide is followed by a guanine nucleotide linearly along its 5' to 3' direction. Cytosine methylation often occurs in CpG islands; hence, finding CpG islands is synonymous to finding cytosine methylation sites. One accurate and fast desktop tool that we can use to identify CpG islands is CpGTLBO (Yang *et al.*, 2017). First, CpGTLBO uses clustering approach to identify CpG island candidates, which effectively cut down the large amount of redundant DNA fragments. Then it uses teaching-learning-based-optimization (TLBO) to accurately predict CpG islands among promising CpG island candidates. CpGTLBO performs more accurate and faster than many CpG island detection methods, that detect based on sliding window and clustering technology, as the accuracy of these methods is proportional to the time required (Yang *et al.*, 2017). Another desktop tool we can use is CpGcluser (Hackenberg *et al.*, 2006), which CpGTLBO (Yang *et al.*, 2017) is built on. This algorithm predicts directly CpG clusters based on the physical distance between neighbouring CpGs on the chromosome. A p-value is given to each of these clusters and the most statistically significant ones can be predicted as CpG islands. As CpGcluser only uses integer arithmetic method, it is a fast and computationally efficient algorithm to predict statistically significant clusters of CpGs. Furthermore, all CpG islands predicted by the algorithm start and end with a CpG dinucleotides, which should be relevant for a genomic feature whose functionality is based directly on CpG dinucleotides (Hackenberg *et al.*, 2006).

Secondary structure is the set of interactions between nucleotide bases, i.e., which parts of strands are likely to bind to each other. In DNA double helix, secondary structure is responsible for the 3-dimensional shape of the nucleic acids. One web-based

tool that we can use is Kinefold (Xayaphoummine *et al.*, 2005). It simulates stochastic folding of nucleic acids on second to minute time scales. Simulations of renaturation or co-transcriptional folding paths are done at the level of helix formation and dissociation in agreement with the seminal experimental results. Efficient predictions of pseudoknots and topologically “entangled” helices are done, taking into considerations due to simple geometrical and topological constraints. Simulations launched are automatically stopped from time to time to allow users to have the freedom to choose to continue incomplete simulations or modify recommended options provided by the server in their initial query. The web server provides detailed output that include a series of low free energy structures, an online animated folding path and a programmable trajectory plot focusing on a few helices of interest to each user (Xayaphoummine *et al.*, 2005). We can use another desktop tool called Unified Nucleic Acid Folding or abbreviated to UNAFold (Markham and Zuker, 2008). This software package combines different programs to simulate folding, hybridization, and melting pathways for one or two-stranded nucleic acid sequences (DNA or RNA). Folding prediction for single-stranded RNA or DNA merges free energy minimization, partition function calculations and stochastic sampling. Images of secondary structures, hybridizations, and dot plots may be computed using common formats. The program computes not only melting temperatures, but also full melting profiles. UV absorbance at 260 nm, heat capacity change and different molecular species’ mole fractions are generated as a function of temperature. The software is “command line” driven. Underlying complied programs may be used independently, or in special combinations with the use of Perl scripts (Markham and Zuker, 2008).

Applications of Sequence Composition

The application of sequence composition is extensive. In this section, four recent studies are highlighted to showcase the applications of sequence composition analysis. Eukaryotic RNA often undergo RNA processing to form mature mRNA, and one of the important steps is splicing, which is to excise the introns from the immature RNA and join the resulting exons. Hence, identifying the intron/exon boundaries on a sequence is useful to computing the resulting peptide from genomic sequence. A study (Zafri and Tuller, 2015) using 4 fungi; *Saccharomyces cerevisiae*, *Schizosaccharomyces pombe*, *Aspergillus nidulans*, and *Candida albicans*; found that intron/exon boundaries often exhibit weak RNA folding and a decrease in GC content. This suggests that current RNA sequence analysis tools, such as RNAfold (Hofacker *et al.*, 1994) and ViennaRNA (Lorenz *et al.*, 2011), may be useful for other purposes.

The ability to predict gene expression from sequence is useful to have (Ling and Poh, 2014), especially when experimentally derived expression data is lacking. A study (Su *et al.*, 2016) proposed to use DNA sequence features; such as histone modifications, DNA methylation, DNA accessibility, transcription factors, and trinucleotide composition; in a support vector machine to predict gene expression. Su *et al.* (2016) achieved a predictive accuracy of 95.96% on human embryonic stem cell line H1, presenting the work as a predictive model for binary classification into high or low expression when experimentally derived expression data is lacking.

Assembly of reads from next generation sequencing experiments often results in large sequence fragments, known as contigs, rather than entire genome. Each contig is considered as an operational taxonomic unit and related contigs needs to be binned together for further analysis. Several software for binning contigs exist and some tools; such as CONCOCT (Alneberg *et al.*, 2014), employed sequence composition in its computation. In this case, sequence composition is used a data point for computation, which acts like a compression of the sequence has the effect of reducing the feature space compared to using raw sequences. Recently, a new tool known as COCACOLA (Lu *et al.*, 2017) that incorporates sequence composition had been proposed, and demonstrated a precision of 99.78% and a recall of 99.93%, compared to precision of 93.43% and recall of 99.6% from CONCOCT.

Many eukaryotes contains accessory chromosomes, known as B chromosomes, in contrast to standard chromosomes or A chromosomes (Houben, 2017). Sequence analysis of several B chromosomes revealed B chromosomes contains DNA originating from standard chromosomes, such as in rye (Klemme *et al.*, 2013). This suggests that B chromosomes may serve an evolutionary purpose and further demonstrates that sequence analysis is an important aspect of evolutionary genetics (Ruban *et al.*, 2017).

Introduction

A genome contains all the necessary information required for a system to function optimally at any given condition. The central dogma skeleton dictates the flow of genetic information from genome to protein via RNA. The 20 amino acids are decoded within the genome using the combination of the four letters of DNA language in three base pair combinations (i.e., triplets of bases), known as DNA codons. One feature of the DNA codons is that the code is degenerate as one amino acid can be coded by more than one codon. Redundancy of the codons can be explained from the excessive 64 possible combination of the four nucleotide base pairs in a triplet base ($4^3 = 64$) to represent the 20 amino acids. As a consequence, only methionine and tryptophan are encoded by a single codon, whereas the other 18 amino acids are encoded by more than one codon. The genetic code table showed that the degeneracy mostly occurred due to variation in the third base of the codons. It is due to this redundancy that different DNA sequences can still produce identical protein sequences, a situation known to be synonymous mutation.

As the DNA sequences become accessible through sequencing, information regarding the codon usage in the coding sequences can be obtained. This data led to the discovery that these codons are not being used equally uniform throughout the genome. Earlier studies have identified the presence of preferred codons to encode for specific amino acids. Variation of choice of codons to represent amino acids is not only observed among species from different taxonomic group, but also showed significant variation among individuals of the same species, across different genes in the same genome and even across regions in the same gene. Nevertheless, the codon bias is most prominent in species from different taxonomic groups even in proteins with identical function. This phenomenon of species-specific codon choice is known as “codon dialect,” which signifies the codon-usage bias observed across different organisms (Ikemura, 1985).

GC Content and Codon-Usage Bias

Earlier, the study of codon usage focused on the DNA composition at the last base pair of the codons, the position where degeneracy mostly occurred. In relation to that, preference of the base content at this location also distinguished the codon bias observed in monocots and dicots. In monocots, 16 amino acids favor G + C at the third degenerate base, whereas in dicots only 7 out of 18 amino acids prefer G + C at this base (Murray *et al.*, 1989; Tyson and Dhindsa, 1995). Nonetheless, when there is C at the second codon's base, both groups of plants avoid G in their last codon's base as dinucleotide combination of CG may result in methylation of the DNA. Dinucleotide combination of CG is not only avoided in plants but also other higher eukaryotes, where methylation plays a role in gene regulation. Preference of base in choice of synonymous codons is known to be related to its GC content. In *Mycoplasma*, which is known to be AT rich at 60%–75%, has codon preferences toward A and T in various coding region (Muto *et al.*, 1986). Furthermore, homologous cDNA of human gene sequences derived from different tissue sample contained 80% amino acid sequence similarity but with significant G + C content variation. In consequences, the sequences were also identified to have significant variation of codon bias, especially at the third codons (Kudla *et al.*, 2009). This observation supports that the total G + C content in genome or within genes is the determinants of the variation in codon usage. This variation is hypothesized to be attributed by the mutational mechanism that directly controlled the GC content throughout the genome (Chen *et al.*, 2004). Positive correlation between the GC content and the codon usage is advantageous as the GC content data can be exploited to predict the reading frame and the coding strands of DNA sequences (Bibb *et al.*, 1984). Recently, a study highlighted the important role of the genome's GC content to influence the genome-wide codon-usage bias in the mammalian cell (Rudolph *et al.*, 2016).

Influence of tRNA Abundance on Codon Bias

Another determinant of the codon-usage variation is the tRNA abundance. As an adapter molecule to link the mRNA to the amino acid in protein synthesis, the abundance of the complementary tRNA molecules are directly related to the frequency of codons (Ikemura, 1985). The investigation was based on the finding that codon bias is the most extreme in highly expressed genes where translational efficiency would be a priority. The finding established a selection-based hypothesis that the selection of optimal codons in a certain gene is a function of the gene's adaptation to the complementary tRNA molecule available to increase efficiency of the protein synthesis. Following this observation, a metric known as tRNA adaptation index (tAI) was developed to analyze the correlation between the abundance of tRNAs and translational efficiency (dos Reis *et al.*, 2004). The metric measures the copy number of tRNA genes, which is assumed to be correlated with tRNA abundance in cells.

It also takes into consideration the efficiency of the binding between the codon–anticodon and the possibility of the imperfect match between the codon–anticodon at the third position (i.e., Crick’s wobble rules) (Crick, 1966). Most importantly, the metric enables genome-wide estimation of translational efficiency through the abundance of tRNAs, which is directly related to codon bias. The metric has been used successfully to predict translation efficiency of 2800 yeast orthologous genes based on the measures of tRNA adaptation to conform the codon usage (Man and Pilpel, 2007). Moreover, the metric has also been shown to be in correlation with the ratio of protein to mRNA level in *Saccharomyces cerevisiae*, which has been able to support the tRNA adaptation hypothesis (Tuller et al., 2010b).

The tRNA adaptation theory to shape the codon composition in genes is not applicable universally across all kingdoms. The hypothesis could explain variation of codon composition in most of the prokaryotes tested (Andersson and Kurland, 1990) but not in eukaryotes. Kanaya et al. (2001) showed that different eukaryotes have different selectional forces to determine their codon composition. In his study, only *Schizosaccharomyces pombe* and *Caenorhabditis elegans* showed positive correlation patterns of codon usage and tRNA gene number. On the other hand, *Drosophila melanogaster* showed the important influence of C or G base in the third codons to shape its codon usage. *Xenopus laevis* and *Homo sapiens* showed the role of isochore structure of mRNA produced to influence their codon composition (Kanaya et al., 2001). It was suggested that multicellular organisms of eukaryotes have higher tRNA gene redundancy, which posits lower selection pressure to compose their codons based on the tRNA availability (Quax et al., 2015). In addition, the disparity of determinants for codon composition may also be related to the different strength of optimal codon bias in eukaryotic genome as was shown in Dos Reis and Wernisch (2009). Nevertheless, recent evidence showed that translational selection (i.e., mechanism of translational optimization based on the natural selection of the codon usage) was identified to be the positive factor contributing to codon bias in housekeeping-genes of human (Ma et al., 2014), contradicting the previous findings (Kanaya et al., 2001). Moreover, the hypothesis is favored by the finding that there is a preference to employ the same tRNA leading to repetitive use of a similar set of optimal codons as a way to optimize translation speed especially in regions of highly expressed genes (Canarozzi et al., 2010). Preferential optimal codons identified in highly expressed genes were also identified to be limited by the availability of tRNAs to increase its translational efficiency (Qian et al., 2012).

Codon Adaptation in Composition of Codon

Composition of codon in genes is known to affect the fate of the protein being synthesized as it influences level of expression, protein folding, and the regulation of protein expression. This observation led to the same common question as the translational selection as discussed above and that is the role of codon bias in determination of the proteins’ expression level. As a consequence, each species has its own set of “preferred codons” identified within the highly expressed genes that is assumed to translate efficiently to ensure optimal protein synthesis. Relative to the finding, a matrix known as codon adaptation index (CAI) was developed to assess the relative adaptation of individual codons encoding a certain amino acid. The index measures the ratio of the codon’s frequency to the frequency of its other synonymous codons. The index was measured from the highly expressed genes as the set of reference and the CAI for a gene can then be derived through the geometric mean of the relative adaptiveness values of all the codon within the gene (Sharp and Li, 1987). Similar to tAI, CAI also enables prediction of gene expression level but on the basis of the choice of codons encoding the gene (Sen et al., 2007; Wu et al., 2005). The index was also shown to be highly correlated to mRNA concentration of most of the genes tested in Coghlan and Wolfe (2000) and in microarray study of Martín-Galiano et al. (2004). Nonetheless, the CAI index has its own caveats to its predictive power. This is due to the fact that the index relies on a set of reference genes to derive its index, which might imposed limited value to predict expression for genes not reflected in the reference set (Martín-Galiano et al., 2004). The index also failed to include other positive factors influencing the expression value of the composed codons (Ermolaeva, 2001). Consequently, few studies showed a disparity of CAI index and the actual expression value of the genes tested (dos Reis et al., 2003; Kudla et al., 2009). Nonetheless, the index is still widely used as a prediction tool especially in de novo gene synthesis, whereby the CAI value is taken into consideration in the codon optimization algorithm (Chung and Lee, 2012; Condon and Thachuk, 2012; Nandagopal and Elowitz, 2011). The algorithm is developed based on several known factors to influence the expression level of genes based on the composition of codons, other than just the CAI. In addition, there are also other indexes developed to predict expression value based on the codon usage. Some of the alternatives to CAI are relative codon-usage bias (Roymondal et al., 2009), expression measure $E(g)$ (Roymondal et al., 2009), relative codon adaptation (Fox and Erill, 2010) and modified relative codon bias strength (Das et al., 2017).

Positive correlation of the codon composition and its expression level implied that synonymous mutation among orthologous gene products, be it across different individuals or tissues, may no longer be considered as silent (Chamary et al., 2006; Kimchi-Sarfaty et al., 2007; Shields et al., 1988). The choice of codons, even though they are synonymous with respect to amino acids they encode, the information determines the mRNA structure and stability and affecting the protein structure, and its folding kinetics. This was depicted in a study when 154 synthetic orthologous genes with various synonymous variants in their codon showed different level of mRNA level and degradation rates (Kudla et al., 2009). It is important to note that the variant was not entirely caused by the composition of preferred codons throughout the genes but due to the variation in the ribosomal binding site that changed the stability of mRNA folding.

Codon Ramp at Translational Initiation

In separate studies, investigation of coding sequences from both prokaryotes and eukaryotes revealed a presence of evolutionarily conserved codon composition known as “ramp” at the 5' end of the sequences (Tuller *et al.*, 2010a). The author highlights the role of codon composition in controlling translation efficiency through codon and tRNA adaptation and also via the presence of codon ramp as a mean to reduce ribosomal traffic jams in the beginning of translation. Even though the feature is evolutionarily conserved across domains of life, the ramp may not be universally present in all genes in every genome but only in highly expressed genes as inspected in the study. It was also suggested that the ramp functions to sense the abundance of tRNAs and changes its ramp's design in response to the different conditions based on the observation that different functional genes contained different design of the ramp. The condition-specific ramp is still an open question and thus far no study has yet validated the claim.

Study of translational efficiency and codon usage advance forward with the emerging new techniques of ribosome profiling. The technique used deep sequencing technologies to profile *in vivo* translation (Ingolia, 2014). By using the approach, a study was able to prove slower elongation rate upon reduction of heavily used tRNA and at the beginning of a message (i.e., ramp) (Pop *et al.*, 2014). Moreover, another two studies were also able to validate the slower translational elongation rate of the nonoptimal or the rare codons that have low respective tRNA population (Dana and Tuller, 2014; Gardin *et al.*, 2014).

Bioinformatics Tools to Analyze Codon Usage

As described earlier, CAI is one of the indexes used apart from several other measures of codon usage. There are a large number of indices that cover a wide area of underlying biological features (Roth *et al.*, 2012). Typically, these indices are used to denote a measure of departure from an expected value, for instance, of codon distribution based on nucleotide frequencies. Similarly, some indices measure the closeness to a hypothetical optimal codon state. In turn, such measures get compared to preferred codon usage of reference set of genes that may be optimal, highly expressed, in a specifically defined group or, on the contrary, genes encompassing the whole genome.

While a large amount of codon measures has been developed, the choice of the index will depend on the goal being achieved as every index has its specific aspect of codon usage being measured. The CAI has been widely used and known for its usage of measuring codon-usage bias (Cannarozzi *et al.*, 2010; Friberg *et al.*, 2004). Several other complementary indices provide a measure of understanding diversity and recommend using an ensemble of features to better classify aspects such as translational efficiency (Roth *et al.*, 2012; Tuller *et al.*, 2010a). Having diverse methods of measuring codon usage requires benchmarks in order to test its statistical performance in achieving the goals comparatively. Some studies have described comparisons across measures, however, the coverage across the many indices available is still lacking (Comeron and Aguadé, 1998; Supek and Vlahoviček, 2005; Suzuki *et al.*, 2008). Partly, this is due to the scarce availability of reproducible computational implementation of those measures by the authors in the form of programming scripts or software.

Nevertheless, there are a few tools that have the ability to calculate the desired indices easily based on DNA sequences. INCA provides the ability to calculate CAI and effective Nc (ENC) besides the ability to apply principal component analysis (PCA), self-organizing maps, and 3D scatterplot to visualize any correlations in the high-dimensional data being presented (Supek and Vlahoviček, 2004). Moreover, Dnasp, a multipurpose population genetics software program, can compute relative synonymous codon usage, ENC, codon bias index, and the scaled chi square (Morton, 1993; Sharp *et al.*, 1986; Shields *et al.*, 1988; Wright, 1990). Other software tools that offer similar calculation of indices are GCUA, ACUA, and CodonW (McInerney, 1998; Peden, 1997; Vetrivel *et al.*, 2007). Most of this software includes some statistical analysis method such as multivariate analysis, PCA, and correspondence analyses (CA). Comparison of statistical methods for CA showed that within-group CA performed well in identifying new factors contributing to variation and horizontal transfers of genes more accurately (Suzuki *et al.*, 2008). To support the use of the analysis, an online resource to perform such analysis is available Pôle Bioinformatique Lyonnais server (Charif *et al.*, 2005).

Bioinformatics Tools to Optimize Codon Usage in DNA

Besides serving the specific purposes to better understand codon variation, researchers may use the principle behind the finding to synthesize artificial DNA. Codon bias does not affect the amino acid sequence itself, nevertheless, it may have impact in protein production. Directly, the biotech application to optimize the DNA sequence is crucial for optimal production of target protein in bioreactors. For such purposes, there are software programs that aid in returning the optimal form of codon usage for a DNA sequence such as DNAworks and OPTIMIZER (Hoover and Lubkowski, 2002; Puigbò *et al.*, 2007). DNAWorks has a standard threshold that it uses in the optimization step to pick the two highest frequency codons for encoding the amino acid. In contrast, OPTIMIZER server provides precomputed tables for around 150 prokaryotic genomes that are found to be under strong translational selection while optimizing all codons while introducing the most minimum changes to the DNA submitted.

Applications in Systems and Synthetic Biology

Through natural selection, optimal codon usages for diverse types of genes and organisms were formed. While the codon optimization field is inevitably moving away from older ideas that synthetic genes should contain mostly of high-frequency codons, the real challenge remains on methods in replicating high protein production for robust production systems in biotechnology. There could be many features that are important for synthetic gene design such as synonymous codon cooccurrence bias, nonsynonymous codon pair bias, tRNA-associated properties, and expression (Quax *et al.*, 2015). However, there is a lack of attention of incorporating these features in synthetic biology. For instance, recording of tRNA-associated properties such as charged tRNA and regular tRNA abundance levels in high protein expression conditions will provide hints for better codon optimization to maintain tRNA levels for increased production of target protein. Besides that, application of the “codon harmonization” principles could be better suited in achieving efficiency in robust yet demanding heterologous production environments (Angov *et al.*, 2008; Quax *et al.*, 2015).

Some of the exciting implications of better rational gene design in synthetic biology are the creation of synthetic biosynthetic pathways, gene circuits, or even entirely new genomes. Realistically, timely expression of functionally networked genes is crucial in the design of such biocircuitry. Some progress made in differential codon bias and differentially expressed prokaryotic cistrons may provide blueprints for designing synthetic operons to express these circuits or pathways (Li *et al.*, 2014; Quax *et al.*, 2013). Moreover, rapid advances in DNA assembly recently allowed the assembly and transplantation of complete synthetic genomes (Gibson, 2014). Essentially, such a protocol enables the redesign of genomes from scratch and allows its reemergence from another compatible host. Nevertheless, better understanding of codon bias could be helpful in the systematic design of an optimally functional synthetic genome by incorporating sensible modules that consider codon usage, tRNA gene levels, and tRNA-modifying enzymes.

Conclusion

The study of translational efficiency and codon usage is still an open debate. Several studies are in support of the selection theory in codon composition while others refuted and claim other features of the mRNAs are more significant to contribute in its efficiency. Nonetheless as technologies advance forward and more techniques prevail, the question demands more evidence to fulfill the answer. The understanding of codon composition is important not only for de novo gene synthesis but to understand the regulation of genes in different conditions, information that seems to be hidden in what used to be a silent mutation. Furthermore, in the future, codon usage principles might find relevance in synthetic biology, for instance in optimizing the production of target proteins.

Identification of Sequence Patterns, Motifs and Domains

Introduction

The development of protein and nucleic acid sequencing has revolutionized our understanding of macromolecular function. Sequence-based analyses are so powerful that it has been estimated that over 95% of our biochemical understanding of the protein function comes from such analyses. The power of sequence analysis is intimately tied to the evolutionary process. While the mutation process is not chemically random, it is random with respect to whether mutations occur in non-coding regions, genes, or regions that encode functionally important parts of proteins (such as active site residues). The process of selection is decidedly non-random; mutations that disrupt vital cellular processes, such as changes in transcriptional regulatory regions, structurally or functionally important parts of proteins, or epigenetic regulation are generally eliminated from the population (i.e., the organism bearing these mutation shows reduced fitness). The result is that structurally and functionally important sequence residues in proteins, the corresponding nucleotides that encode these regions in DNA, and important regulatory factor binding sites in DNA and RNA, all accumulate mutations at a slower rate than less critical regions. These regions thus appear *conserved*, and it is this conservation that is exploited by sequence-based methods for identifying patterns, motifs, and domains. Furthermore, conserved regions can often be directly associated with the specific molecular function that causes their conservation, making them extremely useful for predicting molecular properties from sequence.

In this article we will use the term *motif*, to cover all kinds of motifs, patterns, and domains, and focus on motifs that can be identified in macromolecular sequences. The definition of *motif* in computational biology is essentially the same as in common English usage – “A dominant or recurring idea in an artistic work (see “Relevant Websites section”)”. Sequence motifs can be found because they repeatedly occur, with limited sequence variation, many times in the same molecule or in different molecules. A critical sequence region that occurs only once is very difficult to define and associate with functional information.

Nucleic acid and protein motifs have very different properties. One of the most salient differences is due to the difference in the size of the nucleic acid and protein alphabets, four bases versus twenty amino acid residues. The difference in alphabet size means that, for any specific motif, the background of randomly matching (false positive) sequences will be higher in nucleic acids than in proteins. In addition, the pitch of the DNA helix, 10.4 bases/turn in A-form DNA, suggests that a protein interacting with the base-pairs in the major groove of the DNA can interrogate only five to six consecutive bases (assuming it does not wrap around the DNA); Not coincidentally, many transcription factor binding sites are about six bases long (or dimeric sites with two six base regions). The small alphabet and the short length of nucleic acid motifs makes the identification of such motifs challenging. Proteins, on the other hand have a larger alphabet, and the size of protein motifs is often larger. Structurally, conserved regions of proteins tend to lie in the folded core of the protein; typically a protein chain requires 6–12 residues to cross the protein core, where there are many constraints on acceptable mutations due to the very tight packing of the protein interior. Upon reaching the surface, the chain typically makes a bend or turn and reenters the protein core. The residues at turns and other surface exposed segments tend to show much weaker evolutionary constraints because they are free to move in the solvent. Surface residues also tend to be *hydrophilic* whereas core residues tend to be *hydrophobic*. This pattern of protein structure produces conserved regions that are much longer than in DNA, but which include a certain amount of internal length variation (commonly called *gaps*), due to the less conserved turn and surface regions. It is noteworthy that at surface turns, very large insertions of additional sequence often occur without disrupting the folded structure of the protein. The twenty letter protein alphabet and larger size of protein motifs makes it easier to confidently identify them in practice.

Transcription factor binding sites (TFBS) are the most important class of DNA motifs, due to their importance in gene regulation. Other DNA motifs of interest include transcription and translation start sites, splicing signals, terminator regions (although some of these actually function at the RNA level). Broader sequence patterns such as CG rich “islands”, patterns associated with 3D structure (bending and twisting of the helix), and sequence isochores, local DNA regions with different base composition, have also received attention. Motifs in RNA have received less attention in general, and can be either sequence-based, as in DNA, or related to the formation of internally base-paired structures.

In proteins, sequence motifs have been derived on many different scales ranging from the sites of post-translational modifications (single amino acid residues), active sites (several residues), to domains (dozens to hundreds of residues) and whole proteins (hundreds of residues).

Measuring Classification Quality

Pattern/motif/domain recognition is usually treated as a two-class supervised learning problem where the goal is to label each letter of a sequence, either nucleic acid or protein, as either belonging to a motif (positive), or belonging to a background model (negative). After classification, each letter in the sequence is considered to be true positive (TP; labeled as motif, part of motif), false negative (FN; labeled as background, part of motif), false positive (FP; labeled as motif, part of background), or true negative (TN; labeled as background, part of background), based on comparison to correctly labeled (gold-standard) training data. The success of the classification is measured in the same way as most machine learning methods, i.e., in terms of precision

($TP/TP + FP$) and recall ($TP/TP + FN$). The terms sensitivity, which is the same as recall, and specificity are also used. The definition of specificity is inconsistent in the literature, sometimes being defined as the same as precision, and sometimes defined as the correct negative fraction ($TN/TN + FN$). Precision and recall, since they are unambiguous, are therefore preferred. Usually there are many more negative examples in the training data than positive examples, for example, a gene region may contain only one TFBS (covering 10–12 bases), and tens of thousands of bases of non-TFBS bases. This *class imbalance* means that even methods with very high recall (sensitivity), may not work well in practice because the false positive rate is too high (i.e., low precision). Indeed, a method that only misclassifies 1/1000 of the negative bases, may easily generate far more false positives than true positives.

There is usually a tradeoff between precision and recall. For instance, one may achieve very high recall by simply predicting all bases as belonging to the motif. One may also achieve high precision by predicting only the strongest sites as belonging to a motif, but at the cost of misclassifying many true, but weaker, sites as non-motif. Approaches that consider both precision and recall in evaluating classification quality are preferred over simply looking at the recall since they cannot be “gamed” by tuning a method to be high recall/low precision. The most widely used method that considers both precision and recall is the Receiver Operating Characteristic, ROC (Zweig and Campbell, 1993; Gribskov and Robinson, 1996), and the area under the ROC curve, or AUC. This statistic has an attractive statistical interpretation; AUC is equivalent to a Wilcoxon test and is the probability that a random positive will score higher than a random negative. It is well known that ROC and AUC tend to perform poorly when there is a large degree of class imbalance; in this case, Mean Average Precision, MAP, is often preferred. Another commonly reported measure of classification quality is the F_1 score (also referred to as F-score, F-measure, accuracy, or Sørensen–Dice similarity coefficient), which is the harmonic mean of precision and recall ($F_1 = \frac{2 \cdot \text{Precision} \cdot \text{Recall}}{\text{Precision} + \text{Recall}} = \frac{2 \cdot TP}{2 \cdot TP + FN + FP}$); F_1 considers false positives and false negatives to be equally costly, which is usually not true when class imbalance is large, and can be misleading in many practical situations.

The precision and recall seen on the gold standard training data often overestimates the efficacy of the classification due to *overfitting*. An unbiased estimate of classification quality therefore requires *cross validation*, a procedure in which a portion of the data is not used in training, and held out for use only in testing. It is important that the training and test data be independent; in the sequence motif context this requires that highly similar sequences (probable *homologs*) not occur in both training and test sets. Such sequences are usually identified by screening with sequence comparison programs such as Blast (Altschul *et al.*, 1990, 1997).

Models

When considered as a two-class problem, motif identification considers two feature distributions: the motif, or *foreground*, distribution and the non-motif or *background*, distribution. In a Bayesian context, the background model is the prior probability of the features, and the foreground model is the conditional probability of the features in the model class. The discrimination between these distributions can be measured in many ways, among the most common are log-odds ($\log(\text{foreground}/\text{background})$), and Bayesian posterior probability ($\frac{P_{\text{back}}P_{\text{for}}}{\sum P_{\text{back}}P_{\text{for}}}$). Log-odds statistics are particularly useful as the sum of the values over a series of sequence positions gives the relative probability that the sequence arises from the foreground or background model. The scoring matrices used in sequence alignment and database searching, such as the Dayhoff PAM (Dayhoff *et al.*, 1978) and the BLOSUM (Henikoff and Henikoff, 1992) matrices, are log-odds matrices allowing alignment scores to be interpreted in terms of the relative probability that the aligned sequences are homologous (foreground model) or unrelated (background model).

Background Model

The features are most commonly single amino acid residues, but may be physical-chemical characteristics, probabilities estimated by a prior analysis, or higher order combinations such as words (substrings). For protein sequences, the background model usually assumes that there is no positional correlation between amino acid residues, i.e., that each position is *iid* with respect to all others. While this assumption is known to be incorrect, there are in fact strong correlations between amino acid residues in proteins (in fact these are the basis of many secondary structure prediction methods), it often is sufficient in practice. Another option is to use the observed non-motif sequences to generate the background distribution as in the FastA (Pearson, 1996) sequence comparison program. For nucleic acids, it is well known that there are pronounced correlations between adjacent bases, most notably in the case of the avoidance of CG dinucleotides in eukaryotic sequences. The encoding of protein sequences imposes additional correlations. It is therefore common to use an order 3 to 5 Markov model for the background model. Use of such models is also common in *ab initio* gene modeling where exons, introns, and intergenic regions are separately modeled (most frequently with a 5th order Markov model).

Motif (foreground) Model

Consensus Sequence

Consensus sequence models date to the earliest days of sequencing and are still in use today. Consensus sequences represent a motif as a single sequence where only one base or amino acid residue is permitted at each position. Many restriction enzyme cut sites are effectively modeled in this way (consider, e.g., the *EcoRI* site: $\hat{G}AATC$). As more sequences became available, it was common to use consensus sequences to model promoters and other DNA signals by aligning examples of the signal, and using the

most common base at each position as the consensus sequence (Fig. 1). Such consensus sequences were often referred to as “boxes”, for instance the Pribnow Box (Pribnow, 1975) (now known as the -10 region of the *E. coli* promoter), TATAAT, CAAT (Graves *et al.*, 1986) box, TATA (Lifton *et al.*, 1978) box, and many others.

Because they are concise, consensus sequences are often shown in the literature to mark the position of a motif in a sequence. However, they are a very weak method for motif identification. First, they discard all information about the frequency of the letters at different positions of the motif. For instance, in the consensus sequence for the *E. coli* promoter, TATAAT, the final T is almost 100% conserved, indicating it has very high functional significance. On the other hand, the T at the third position, is not even present in a majority promoters – A, C, G, and T occur almost equally, indicating that this position is essentially irrelevant. Second, consensus sequences do not include a background model – overprediction of promoters in regions that are simply A/T rich is common – consensus sequences do not take into account that a sequence such as TATAAT occurs much more frequently at random in A/T rich regions. Third, consensus sequence do not generalize well. Only a fraction of known sequences precisely match the consensus sequence, and allowing mismatches or *gaps* greatly increases the number of false positive predictions, a problem that is exacerbated by the loss of information discussed, above.

Regular Expression

Regular expressions address some of the inadequacies of consensus sequences by admitting the possibility of several different letters matching at each position of the motif, and by allowing a limited number of variable spaces within the motif. The most important collection of regular expression patterns is found in the Prosite (Xenarios, 2013) database. Because of its high visibility, the Prosite syntax is probably the most widely used for protein sequences (Fig. 2), and is often used for nucleic acid sequences, as well. For the promoter sequence described above, we could write a regular expression such as [TC]-A-X-[AT]-{G}-T, and the combined -35 and -10 regions of the promoter could be written as T-T-[GT]-[CA]-{G}-[AT]-X(16,18)-[TC]-A-X-[AT]-{G}-T (compare to Fig. 3).

One of the advantages of regular expression representations is that efficient algorithms for identifying matches to regular expressions in text corpora are available in most programming languages, and in the UNIX operating system (*grep*). In principle, disregarding setup time, regular expression matching can be $O(n)$, where n is the length of the corpus.

In spite of their superiority to consensus sequence representations, regular expression representations suffer from similar problems. Although multiple characters can be allowed (or forbidden) at each position, there is no way to distinguish between letters that are allowed at very different frequencies (for instance the difference in the frequency of C and T in the first position of the -10 element in Fig. 3 (Oliphant and Struhl, 1988)). Regular expressions also do not incorporate a background model, and permitting incomplete matching typically gives rise to huge numbers of false positive matches. In spite of these drawbacks, the excellent compendium of functional motifs found in the Prosite database (ProDoc) has provided a fundamental resource for both protein annotation and validation of sequence matching algorithms.

Regular expression matches are usually evaluated as simply a match or non-match, and the regular expressions in databases such as Prosite are manually tuned to provide high recall and precision. Calculating the exact probability of matching to regular expressions is complex (see [Sewell and Durbin \(1995\)](#)), but it is clear that allowing even a single unmatched position often dramatically increases the number of false positive matches, causing a great reduction in match precision.

Position Specific Scoring Matrix

PSSMs, also known as Positional Weight Matrices, PWM, and Position Specific Weight Matrices, PSWM, represent motifs as a vector of values for every possible character at each position of the motifs. In literature, PSSMs are often shown with the columns corresponding to positions and rows corresponding to the possible letters; computationally they are more often transposed so that the rows correspond to sequence positions and the columns to letters. The values in the PSSM can be of several kinds – among the most common are: simple counts, probabilities (i.e., each column sums to 1), or log-odds scores (log of the relative probabilities of the character in positive examples of the motif divided by the probabilities of the character in a background model). PSSMs retain all position independent information present in the training data, but do not incorporate information about correlated positions. PSSMs can be matched with sequences using dynamic programming alignment approaches [EPS30004], with complexity $O(nm)$ time, where n is the length of the database, and m is the number of positions in the motif PSSM. Empirical analysis suggests that the score distribution for PSSMs follows an extreme value distribution, similarly to local dynamic programming alignments ([Altschul and Gish, 1996](#)). The term profile (see next section) is sometimes used for PSSMs, although this usage is confusing.

Profile

Profile ([Gribskov et al., 1987](#)) and Profile Hidden Markov Models, PHMMs, are PSSMs that have additional information representing position-specific the weights/probabilities of insertion/deletion. For PHMMs, this additional information specifies the transition probabilities between the match states (which have the position specific probabilities of the letters) and to and from insert and delete states. Some kinds of profiles/HMMs contain additional information describing probabilities of insertion and deletions, resulting in additional columns. In order to keep the file human-readable, these motif representations may use more than one line per position in the sequence. Profiles and PHMMs can be matched using the same kind of dynamic programming algorithms used for PSSMs ([Wang and Dunbrack, 2004](#)), but it is customary to discuss PHMMs in terms of the Viterbi ([Viterbi, 1967](#); [Rabiner, 1989](#)) and Baum-Welch ([Baum et al., 1970](#)) algorithms.

Large molecular structures, such as protein domains, are most often defined using the profile approach because of the incorporation of positions specific indels in such models. In general, whole proteins and proteins domains may have insertions at any sequence position exposed on the surface of the protein – such large indels are seen in many families (see, for instance, for instance the ubiquitin specific protease family ([Ye et al., 2009](#))).

Sequence Logos

Examining and discerning the pattern of conservation in a PSSM or profile is difficult due to the large number of values. Sequence Logos ([Schneider and Stephens, 1990](#)) are a widely used graphical representation in which the letters at each position of the motif are displayed with different heights depending on their conservation. Conservation can be measured in a variety of ways such as letter frequency or information content ($H = -\sum_i p_i \log p_i$).

Learning Approaches

Multiple Alignment Based

Many motif learning approaches rely on multiple sequence alignments [EPS30005], MSAs, as a starting point. Several issues with MSAs affect one's ability to extract motif descriptions from MSAs.

One of the most important concerns is sampling. Even today, when thousands of complete genomes have been sequenced, the motif training data (i.e., the known sequences) is often very uneven with respect to the range of taxa from which sequences are drawn, and with respect to the presence of many close homologs (or even exact duplicate sequences). If not dealt with, these sampling issues tend to bias the motifs towards certain subclasses of sequences, and may compromise the ability of the learning algorithm to generalize. There are two main approaches to address sampling bias: selecting a less biased subset of sequences for training, or weighting sequences according to the amount of independent information they contain. Selecting a representative subset of sequences with less bias can be done manually, usually relying on taxonomic or other external information (for example, biochemical or structural properties of proteins), or automatically based on pairwise sequence comparisons. One of the most popular automatic methods is CD-HIT (Li *et al.*, 2001), see Fig. 4. Clearly this approach does not produce a completely unbiased representative set since the original distribution of sequences still has a strong effect.

Many methods have been successfully used for sequence weighting (Sibbald and Argos, 1990; Henikoff and Henikoff, 1994; Thompson *et al.*, 1994a,b). Many approaches rely on a distance-based tree [EPS10149], calculated using alignment scores from pairwise alignments or the MSA. The method introduced by Thompson *et al.* (1994a,b) in the Clustal V multiple alignment program, and Henikoff and Henikoff's position-based sequence weights (Henikoff and Henikoff, 1994), which do not require a tree, have been widely used (Fig. 5).

Position specific weights are first calculated for the letters at each aligned position in each sequence. The weight is

$$w = \sum_{p=1}^{LENGTH} \sum_i^{alphabet} \frac{1}{k_p n_{i,p}}$$

where k_p is the number of distinct letters at position p , and $n_{i,p}$ is the number of occurrences of letter i at position p

While the use of weighting to account for sampling bias is widely accepted, it does not appear that the weights need to be highly accurate, probably due to the high degree of biological variation in evolutionary rates.

In addition to bias, sequence training sets may also suffer from undersampling – the total number of sequences may be small, and letters/words that occur at very low frequencies are not observed. This problem is often treated by replacing the observed letter counts with a modified count that includes a pseudocount or prior. One common adjustment, commonly called a “plus one prior” is to add one to every letter count. Unless the total counts are very large, such a pseudocount is probably an overcorrection. Another common approach is to add one letter count distributed according to the overall letter distribution (i.e., the pseudocount sums to one across all letters).

Another concern with MSAs is the presence of errors in the alignment, especially near to insertions and deletions. In the case of regular expression representations, misalignment can be a severe problem and causes serious degradation of both precision and recall. The misalignment issue is exacerbated by the inclusion of sequences with errors, very distantly related sequences, or even sequences that are unrelated, in the training set. The latter problem is more frequent than one might think because training sequences are often selected by noisy biological criteria (such as co-expression) – the presence of incorrectly labeled training examples is therefore very common in biological contexts.

Consensus sequences and regular expression motif descriptions usually focus on short, highly conserved sequences. Often these are selected manually (see “Relevant Websites section”), based on an initial multiple alignment and/or expert knowledge, followed by

Fig. 4 Sequence weights. The tree shows a group of globin proteins (Thompson *et al.*). A. position-based weights, un-normalized. B. position-based weights, normalized to sum to 1. C. Clustal tree-based weights, un-normalized. D. Tree-based weights normalized to sum to 1.

1. Measure similarities between sequences using Blast or a dynamic programming alignment
2. For each sequence, determine the number of neighbors. Sequences are neighbors if their alignment score is higher than a user selected threshold
3. Find the available sequence with the most neighbors and add it to the representative set.
4. Mark all of its neighbors as unavailable
5. Repeat 3-4 until no sequences remain available

Fig. 5 CD-Hit method of selecting unbiased representative sequences.

iterative database searching to validate that the pattern separates positive and negative examples. A problem with this manual approach is that it may not generalize well because only letters that occur at a position, in the training data, are included in the pattern. A new sequence that contains a chemically similar but novel amino acid residue may therefore not be recognized. In addition, as true positive examples accumulate, with continuing growth in the number of sequences, one typically finds that an increasing number of letters are allowed at each position leading to a concomitant increase in false positive matches (i.e., lower precision). This problem is typically solved by splitting the pattern into two more specific patterns that each recognize a subset of the training examples.

Generalization, the ability to detect examples of a motif that do not precisely match any of the training examples is one of the primary goals of motif identification. Generalization is particularly difficult when the number of training examples is small, or drawn from a limited taxonomic range so that the sequence diversity is low. A common approach to this is to use external knowledge about the chemical/mutational similarity of the amino acid residues to augment the training observations. This approach has been called *regularization* (Karplus, 1995), although it differs significantly from the L_1 and L_2 regularization approaches typically used in machine learning to restrict the complexity of the model parameterization [EPS30012]. In the case of regular expression patterns, regularization often augments the set of allowed letters observed at a position with additional letters that are chemically similar, but were not observed. For instance, it is common to predefine classes of amino acid residues such as hydrophobic = [ILMV], basic = [HKR], aromatic = [FWY], acid/amide = [DNEQ], hydrophilic = [HKRDNEQSTWY], etc. A column in a multiple sequence that contains, for instance, Isoleucine (I), Methionine (M) and Valine (V), might be defined as belonging to the hydrophobic class [ILMV], even though Leucine (L) was not observed. A more sophisticated approach, incorporated in the EMotif program (Huang and Brutlag, 2001; Nevill-Manning *et al.*, 1998) matches multiple overlapping classes to the observed set of letters and chooses the best matching class. These approaches are regularizations in the sense that they reduce the original 5×10^{18} possible character classes to around 10 classes.

For PSSMs, mixture models based on empirical observations of amino acid substitutions are commonly used. Fitting the observed data to a Dirichlet mixture distribution is a common approach. A mixture distribution is a weighted combination of simpler base models, in this case the base models are Dirichlet distributions. The probability of the “true” letter distribution at a position $P(\vec{x})$ is given by

$$P(\vec{x}) = \frac{\sum_j w_j P_j(\vec{x})}{\sum_j w_j}$$

where the $P_j(\vec{x})$ are the probabilities predicted by the base models and w_j are weights that indicate the importance of the model in the mixture. $P_j(\vec{x})$ is a Dirichlet distribution.

$$P(\vec{x}) = \frac{\sum_{i=1}^{20} p_i^{x_i-1}}{Z}$$

where the p_i and w_j are empirically determined based on known “good” multiple alignments drawn from the BLOCKS database, HSSP, or expert protein family multiple alignments (Brown *et al.*, 1993; Sjölander *et al.*, 1996).

For a vector of observed letter counts, $\vec{n}$, and M base Dirichlet distributions, the estimated true frequency of letter i , $\hat{P}(x_i)$

$$\hat{P}(x_i) = \sum_{j=1}^k P(\vec{\alpha}_j | \vec{n}) \frac{n_i + \alpha_{ij}}{|\vec{n}| + |\vec{\alpha}_j|} = \sum_{j=1}^M \left(\frac{w_j P(\vec{n} | \alpha_j)}{\sum_k w_k P(\vec{n} | \alpha_k)} \right) \frac{n_i + \alpha_{ij}}{|\vec{n}| + |\vec{\alpha}_j|}$$

Another approach to learning a PSSM is the evolutionary profile (Gribskov and Veretnik, 1996), in which the Dayhoff PAM evolutionary model is used as a source of known biological patterns of residue substitution. Briefly, for each column in the alignment, the probability of the observed letter frequencies expected for each possible ancestral residue, at different evolutionary distance from 1 PAM to 1024 PAM, are used to choose the components of a mixture model, weighted by the probabilities. The mixture probabilities are then used to form log-odds scores using expected random frequencies of the letters as the background. This approach has also been generalized to use a continuous estimate of the evolutionary distance rather than a fixed set of PAM matrices (Eskin *et al.*, 2001).

In some cases, either due to a poor multiple sequence alignment, or because of biological or functional divergence within the set of training sequences, an aligned position may represent two or more distinct patterns of conserved letters. When this occurs, it has been argued that is desirable to replace the actual observed letter frequencies (or pseudocount) with the probabilities that are dominated by the probabilities derived from a known, biologically relevant, prior distribution. This approach was termed the megaprior heuristic (Bailey and Gribskov, 1996), and has been implemented in MEME, evolutionary profiles, and HMMs.

Non-Alignment Approaches

Protein motifs are most commonly extracted from an initial multiple sequence alignment, but sometimes the training sequences are not strictly homologous, or the sequences contain repeated sequences, rearrangements, or other common situations that disrupt alignment approaches. For nucleic acid sequences, it is usually difficult or impossible to construct an accurate multiple alignment due to the small nucleic acid alphabet, four letters, and the rapid evolution of non-coding regions (such as promoter or enhancer regions in which one might want to find transcription factor binding sites). In these cases, it is necessary to use a learning approach that simultaneously learns both the motif locations and the motif pattern itself. The most widely used approaches, expectation maximization and Gibbs sampling, learn a PSSM motif, without gaps, based on a set of training sequences.

Expectation-Maximization is a general purpose optimization approach that learns a locally optimal pattern that maximizes the probability of the data given the pattern, i.e., the likelihood. With sequences, the pattern is a PSSM giving the probability of each letter at each position of the motif for a pre-determined motif length. EM, as the name implies, is an iterative two-stage algorithm. In the first step, given the current pattern, the probability that each position of each sequence was generated by the pattern is calculated. In the second, the pattern is re-estimated based on the probabilities determined in the first step. The probability weighted frequencies of the letters at each position of the PSSM represent the maximum likelihood estimate of the pattern. The updated pattern is then used to recalculate the probabilities that each position is a site, and the two step process iterated to convergence. The total likelihood is guaranteed to remain equal or increase at each iteration so this can be recognized as a greedy, local hill-climbing, process. EM has a number of advantages: it needs little or no prior information about the pattern to be found (except its length), it typically converges rapidly, and it is adaptable to many kinds of patterns including repeated patterns and patterns that are not present in every sequence. It also has disadvantages: it is a locally optimal method, it is sensitive to initial conditions, and the width of the pattern must typically be known in advance. Typically EM approaches overcome the issues of local optimality and sensitivity to initial conditions by repeating the training multiple times using randomized initial conditions each time. Patterns with the highest total likelihood, or that are found repeatedly, are assumed to be the globally optimal solution (although obviously one cannot be sure).

The MEME program (Bailey and Elkan, 1994) incorporates several clever enhancements that improve the performance of this general EM approach with biological sequence motifs. The first insight is that the desired conserved motif must be present in the training set. Rather than using randomized initial PSSMs, MEME comprehensively samples sequences from the training set and creates the initial PSSMs by mixing the sequence with the background frequency distribution. Then several cycles of EM are performed and the partially trained PSSMs are inspected to identify which ones are converging, taking advantage of the rapid convergence of EM; only these PSSMs are iterated to convergence. The second issue has to do with the motif length. Since this is an input parameter for the EM, the only option is to sample a large number of lengths and to choose the length that maximizes the likelihood (including a correction for model complexity). Finally, especially when considering gap-free motifs, most training sets contain multiple motifs – for instance, two conserved motifs with a variable spacing, such as the *E. coli* promoter, cannot be learned as a single PSSM. To solve this problem, MEME iteratively identifies multiple motifs, and uses probabilistic erasing to remove each motif from the training data after it is discovered. In probabilistic erasing, after the PSSM has converged, the probability, $P(S_{ij}/\text{PSSM})$, that each position, j , of each of the training sequences, S_i , was generated by the motif is evaluated, and the weight of that position is decreased to $1 - P(S_{ij}/\text{PSSM})$.

Another method for learning both the motif and the motif locations is the Gibbs sampler (Lawrence *et al.*, 1993) (GS), which uses a Markov chain Monte Carlo (MCMC) sampling approach. GS can be looked on as a stochastic version of EM. As with EM, a motif width, W , is defined. Each width W word in each sequence is a possible location of the motif, and the probability of each of these positions is calculated identically to the E-step in EM. The probability of generating each word assuming some background distribution, for instance the random expected frequencies of the bases or amino acids, is also calculated. The ratio of these probabilities can be considered to be weights on each possible width- W word. The initial PSSM is constructed by randomly selecting words according to these weights, and at each step, one word is randomly replaced, the probabilities and weights recalculated. This is very similar to the process used in EM, but rather than using the probabilities of all words across the sequences, only a specific group of sampled positions is used. GS is typically slow to converge, often requiring thousands of cycles for even modest numbers and lengths of sequences. Extensions to the original GS procedure that allow multiple motifs to be learned, and that allow the motif width to be optimized have been developed (Neuwald *et al.*, 1995).

Because of the small nucleotide alphabet, motif finding in nucleic acids often incorporates the identification of kmer words that are statistically overrepresented in a training set, where k is typically in the range of 5 to 8 bases. These approaches are widely used, for instance, in defining promoter elements and transcription factor binding sites (TFBS). Because all words are evaluated, word based methods have the theoretical advantage of discovering a globally optimal pattern rather than the locally optimal patterns found by EM and GS. In practice, the advantages are less clear due to the pronounced word preferences of nucleic acid sequences, and the weak conservation of many DNA motifs. Because of the relatively strong word-preference of DNA sequences, even in non-conserved regions, it is critical to include a background model; typically a 5th or 6th order Markov model is used (Sinha and Tompa, 2002). An important issue with word probability based methods is that any ambiguity in the motif, such as a position which is not highly conserved, splits the occurrences of the motif into multiple words. Clearly, this weakens the distinction between the conserved words and the background, reducing the chance that the motif will be detected as significantly overrepresented. In principle one can identify words that represent ambiguous images of a conserved site (Pavesi *et al.*, 2004) but it remains difficult to distinguish such ambiguous patterns. Because of their short length, and the small alphabet, it is common to try to use additional information to constrain the patterns that are identified. The most common constraint has been to require an internal dyad symmetry (van Helden *et al.*, 2000), since many DNA binding proteins possess such symmetry. Most word-based approaches, similarly to PSSM-based approaches, also assume that the positions of a motif are independent which is not necessarily correct.

Validation

Assessment of the classification ability of a program has been one of the most difficult areas in both computational and systems biology. Gold standard data are, themselves, often calculated by a computational learning method. A new method that is better, appears to make many false positive label assignments when compared to an older inferior standard. Still, just assigning more class

labels, or predicting more positives, measures only the recall of a method and says nothing about precision. As discussed above, this leads to serious overestimation of the usefulness of a method. With protein motifs it has been common to use two kinds of standards. The first approach relies on the documentation associated with the PROSITE database, much of which is carefully hand curated. Although PROSITE signatures are based on these data, the data include annotations of false negatives, that is, sequences that should be positive but did not match the PROSITE signature of pattern. This inclusion of both the easy positives (that can be identified with regular expressions), and the difficult positives, which cannot, has made the PROSITE annotation very useful. Another approach is to use the three-dimensional structure databases CATH (Dawson *et al.*, 2017) and SCOP (Fox *et al.*, 2014) to define groups of related proteins. While it is still not clear that all proteins with similar three-dimensional structures are actually related, or whether some protein folds are somehow just energetically favorable, a classification method with the highest recall/precision vs the structural classification is still likely to be the best. For nucleic acid motifs, validation vs gold standard data is more problematic. While a number of compendia of promoter sites and TFBS exist, the counts for particular motifs are often low, and the motifs themselves have often been identified by the multiple alignment or overrepresented word approaches described above. In a few cases, laboratory experiments have been conducted to find short oligonucleotides that physically bind to specific proteins, or that can be pulled down by their bind (as in ChIP-Seq). These datasets are still somewhat difficult to interpret since the exact binding site is usually not determined, and because most sequence-specific nucleic acid binding-proteins have also have high non-sequence specific binding, as well.

Epigenetics: Analysis of Cytosine Modifications at Single Base Resolution

Malwina Prater and Russell S Hamilton, University of Cambridge, Cambridge, United Kingdom

© 2019 Elsevier Inc. All rights reserved.

Introduction

All DNA nucleotides can undergo covalent modifications *in vivo*, with 5-methylcytosine (5mC) being the most investigated and understood of the modifications. In eukaryotes, 5mC is most commonly methylated in a CpG context, however it can also be modified in non-CpG contexts (CHH and CHG methylation) (Guo *et al.*, 2014). Other known DNA nucleotide modifications include adenine that can be converted to N6-methyladenine (6mA), and thymine to 5-hydroxymethyluracil (5hmU) (Sood *et al.*, 2016).

With the advent of next generation sequencing, it is possible to interrogate DNA modifications on a genomic scale and at single base resolution. In this article, we outline methods for interrogating cytosine modifications with particular emphasis on the important and emerging interest in 5-hydroxymethylcytosine (5hmC), 5-formylcytosine (5fC) and 5-carboxylcytosine (5caC) and the downstream bioinformatics analysis.

Some of the existing methylation data including 5mC, 5hmC and 5caC generated by large epigenetic-focused consortia can be viewed and downloaded. Among these, BLUEPRINT is a key player in sharing DNA methylation data, providing a database to browse and download raw data, analysis files or explore data on the BLUEPRINT Data Analysis Portal. Genome tracks are also provided for visualizing the data in UCSC or Ensembl. Other epigenetic data consortia that can provide DNA methylation data (mostly WGBS-seq) include NIH Roadmap, ENCODE and International Human Epigenome Consortium (IHEC) (Adams *et al.*, 2012; Bernstein *et al.*, 2010; Consortium *et al.*, 2012). DeepBlue Epigenomic Data Server enables centralized access to these and more databases (Albrecht *et al.*, 2017).

It is worth noting that nucleotide modifications are also found in RNA molecules (Frye *et al.*, 2016). Many of the analyses outlined in this article will be applicable to RNA, however we focus our attention to the cytosine modifications in DNA.

Cytosine Modifications

The covalent modifications of cytosine of greatest biological interest are to the 5' position. These modifications are of particular interest as they have been shown to regulate development and disease, and more recently aging. Correlative DNA methylation levels at specific loci proved to be valuable tool for predicting the speed of aging in human and mouse (Horvath, 2013; Stubbs *et al.*, 2017). The concept of epigenetic clock was taken a step further into development of commercial test, that is now available to individuals (see Section Relevant Websites).

Starting from unmodified cytosine, a series of enzyme driven reactions lead to 4 distinct modifications and can be returned to an unmodified cytosine (Fig. 1). 5mC is established *de novo* by DNA methyltransferase enzymes (DNMTs): DNMT3a, DNMT3b and DNMT3L (Goll and Bestor, 2005), and its maintenance is controlled by DNMT1 (Delgado-Olguín *et al.*, 2012; Liang *et al.*, 2002). 5mC can be reversed to unmodified C via two alternative mechanisms: passive demethylation as a consequence of lack of maintenance as the cells replicate; or active demethylation, which involves oxidative DNA demethylation mediated by ten-eleven translocation (TET) family of enzymes (Kohli and Zhang, 2013). TET enzymes (5mC hydroxylases) can catalyze the stepwise oxidation of 5mC to 5hmC, 5fC and 5caC (He *et al.*, 2011; Ito *et al.*, 2011; Tahiliani *et al.*, 2009). The conversion of 5fC and 5caC to unmethylated C is thought to be facilitated by excision of modified cytosine by thymine DNA glycosylase (TDG), followed by base excision repair mechanisms (BER) (Weber *et al.*, 2016).

5-methylcytosine: 5mC

The addition of methyl group to the 5' position of cytosine in 5mC is stable and has been shown to play important role in development, tissue specificity, aging and disease. The majority of methylation in mammals occurs in a CpG context, which are distributed non-randomly (Guo *et al.*, 2013, 2014). Most of the mammalian genomes are methylated (Li and Zhang, 2014), but CpG island regions (CGIs) with high density of CpGs usually remain unmethylated and are predominantly associated with gene promoters. Methylation of cytosine is associated with silenced chromatin, but the role of DNA methylation depends on its location within the transcriptional unit. In general, highly methylated DNA in close proximity to the transcription start site is associated with long-term silencing of genes (Raynal *et al.*, 2012). In contrast, methylation of the gene body is associated with transcriptional activity and alternative splicing (Ball *et al.*, 2009; Hahn *et al.*, 2011). Interestingly, 5mC can inhibit binding of methylation-sensitive transcription factors to their target sites, and also promote binding of others, especially those involved in embryonic and organism development (Yin *et al.*, 2017). A further biological role of 5mC is the regulation of imprinted genes (Paulsen and Ferguson-Smith, 2001). The 5mC is also thought to have protective role for genome stability and to act as a defense mechanism against transposons (Bourc'his and Bestor, 2004; Lavie *et al.*, 2005; Turelli *et al.*, 2014; Walsh *et al.*, 1998). It is also clear that 5mC and histone modifications crosstalk, but in mammals this relationship is complex and interdependent (Du *et al.*, 2015; Li and Zhang, 2014).

Fig. 1 Cytosine can be methylated at the 5th position by DNA methyltransferases: Dnmt1 as a maintenance process, or *de novo* by Dnmt3a or Dnmt3b. Resulting 5mC bases can be iteratively oxidised by TET enzymes in the process of active demethylation, resulting in 5hmC, 5fC and finally 5caC products. In the process of passive dilution (PD), 5hmC (and similarly 5fC and 5caC, not shown) can be demethylated to C during the course of DNA replication. 5caC, and also 5fC, can be deaminated to thymine and excised by thymine DNA glycosylase (TDG). The abasic site can be filled with unmodified deoxycytidine triphosphate (dCTP) by the base excision machinery (BER).

5-hydroxymethylcytosine: 5hmC

Recent years have brought evidence that 5hmC is not only an oxidation product of 5mC, but is chemically stable, with a distinct distribution in the genome, forming a stable epigenetic mark in its own right (Bachman *et al.*, 2014). In Embryonic Stem Cells (ESC) cells, 5hmC is enriched at differentiation-associated enhancers (Madzo *et al.*, 2014; Sérandour *et al.*, 2012; Stroud *et al.*, 2011; Szulwach *et al.*, 2011) and bivalent promoters of genes repressed at ESC cells, but activated upon differentiation (Wu *et al.*, 2011). 5hmC is also hypothesized to have a role in protection of genome integrity by marking sites for DNA damage (Kafer *et al.*, 2016). Levels of 5hmC are very tissue specific, with highest prevalence in central nervous system (brain). The differences in 5hmC levels within brain itself are pronounced enough to distinguish between specific brain regions (Lunnon *et al.*, 2016; Spiers and Hannon, 2017).

5-formylcytosine: 5fC and 5-carboxylcytosine: 5caC

The functions of 5fC and 5caC are still unclear, but recent research hints that they may be more than mere oxidation products. In mouse ESCs, 5fC is enriched in enhancer regions marked by H3K4me1 and H3K27ac (Iurlaro *et al.*, 2016). Furthermore, 5fC and 5caC have been shown to affect the rate and substrate specificity of RNA polymerase II processivity (Kellinger *et al.*, 2012; Wang *et al.*, 2015). Chromatin modifiers and transcriptional regulators have been identified as proteins binding to 5fC, suggesting a potential role of 5fC in gene regulation (Iurlaro *et al.*, 2013). Although the role of 5caC still needs to be elucidated, it has been hypothesized to be involved in regulating alternative splicing via CTCF preferential binding to 5caC (Marina and Oberdoerffer, 2016; Spruijt *et al.*, 2013).

Experimental Methods to Assay DNA Modifications in Genome

Bisulfite conversion alone can no longer claim to be a gold standard in 5mC detection as it co-detects 5mC and 5hmC modifications, leaving a confounded signal. To address this limitation of bisulfite-only conversion, several methods have been developed to distinguish between the distinct cytosine modifications (with focus on 5mC and 5hmC). A recent review compares a selection of 5hmC specific profiling techniques (Skvortsova *et al.*, 2017), in this article we focus on techniques compatible with 5hmC, 5fC and 5caC profiling (Table 1).

Bisulfite and oxidative bisulfite sequencing is able to discriminate between 5mC and 5hmC. In standard bisulfite conversion (BS), both 5mC and 5hmC are protected and are read in sequencing as C. The oxidant *potassium perruthenate* is used to convert 5hmC to 5fC, which is read as T in sequencing after BS conversion (same as unmethylated C, 5fC and 5caC) (oxBS). 5hmC levels

Table 1 Comparison of methods for assaying cytosine modifications using array or next-generation sequencing platforms

Description	Detection of										Modified base sequenced as					Depth of seq required	Limitations	Comments/Strengths					
	5mC					5hmC					5fC								5caC				
	Y	Y	Y	Y*	N	T	C	BS: C, oxBS: T	T	T	Y	low	850k	N	oxBS-redBS does not differentiate between 5caC and unmodified C; human only				cost-effective				
EPIC array	Hybridisation of BS/oxBS DNA to arrays	Y	Y	Y*	N	T	C	BS: C, oxBS: T	T	T	Y	low	850k	N	oxBS-redBS does not differentiate between 5caC and unmodified C; human only	cost-effective							
RRBS-seq/RRHP	MspI digestion, Library prep amplification, NGS	Y	Y	Y*	N	T	C	BS: C, oxBS: T	T	T	Y	mid	~12 M	Y	oxBS-redBS does not differentiate between 5caC and unmodified C; Position limited by proximity to enzymes' recognition sites	cost-effective							
WG	Evaluates methylation levels of almost all CpGs	Y	Y	Y*	N	T	C	BS: C, oxBS: T	T	T	Y	high	28 M	Y	oxBS-redBS does not differentiate between 5caC and unmodified C; high cost	Compatible with single cell as input (not for OxBS due to coverage limitations)							
Targeted	Enrichment/library prep -> NGS	Y	Y	Y*	N	T	C	BS: C, oxBS: T	T	T	Y	mid	Kit defined	Y	oxBS-redBS does not differentiate between 5caC and unmodified C	cost-effective							
MeDIP-seq	Anti - 5(h)mC antibody to methylated CpG sites followed by NGS	Y	Y	Y	Y	-	-	-	-	-	N	mid		Y	Biased toward hypermethylated regions, not suitable for very low 5hmC, 100 bp resolution; Limited by antibody specificity	bisulfite-free							
TAB-Seq	5hmC labelling with b-GT, TET oxidation, BS conversion, NGS	Y	Y	N	N	T	BS: C, TAB: T	C	T	T	N	high		Y	Accuracy limited by efficiency of Tet enzyme	limitations of using enzymes							
PacBio SMRT	Direct detection of modified bases by assessing activity of DNA polymerase	Y	Y	Y	Y	C	5mC	5hmC	5fC	5caC	N	high		Y	High cost, throughput limitations	bisulfite-free; no DNA amplification, long reads, multiple modifications detected							
Nanopore	Direct detection of modified bases via ion current as passes through pore	Y	Y	Y	Y	C	5mC	5hmC	5fC	5caC	N	high		Y	High error rate, processivity/throughput, cost	bisulfite-free; long reads, multiple modifications detected							

*Indicates with redBS.

can be quantified by subtracting BS from oxBS signals for each cytosine position (Booth *et al.*, 2012). An associated method to map 5fC is redBS-seq, which utilises chemical reduction of 5fC to 5hmC using *sodium borohydride* (Booth *et al.*, 2014). As a result, 5fC is read as C after BS conversion (same as 5hmC and 5mC). Thus, 5fC levels can be quantified by subtracting redBS from the BS signal. Whole genome sequencing of oxBS and redBS provide the most accurate and least biased 5hmC distribution across the genome, but the associated sequencing costs are very high due to high coverage requirements. OxBS and redBS treatments are also compatible with arrays (e.g., Illumina 450K and EPIC arrays) or in combination with Reduced Representation Bisulfite Sequencing (RRBS) and enrichment methods (e.g., Roche Nimblegen SeqCap) (See [Table 1](#)) (Gross *et al.*, 2016; Spiers and Hannon, 2017; Stewart *et al.*, 2015). The enrichment methods provide a more cost-effective way of assaying methylation levels than for whole genome. BS/oxBS sequencing, however, is not the only method to interrogate 5hmC distribution at a genome scale. TAB-seq, detects 5hmC directly by converting 5hmC to 5-glucosylmethylcytosine with β -glucosyltransferase first (read as C), followed by oxidation of 5mC and 5fC to 5caC by TET enzymes, and BS-seq (Yu *et al.*, 2012a,b). A subtraction of the 5hmC from the BS signal is required to call the 5mC. Several methods to map 5fC and 5caC have been proposed, including *M.SssI* methylase-assisted BS-seq (MAB-seq and caMAB-seq) and chemical-modification-assisted bisulfite sequencing (fCAB-seq and caCAB-seq). Single base resolution methods are mainly bisulfite or enzyme conversion based, but recently novel technologies with the ability to directly detect nucleotide modifications have been developed (e.g. Pacific Biosciences SMRT and Oxford Nanopore) (Rand *et al.*, 2017; Simpson *et al.*, 2017; Song *et al.*, 2012a). These methods currently do not have the per cytosine accuracy of, for example, bs/oxBS, however are likely to be the methods of choice in the future and are introduced further in the Discussion. Although bisulfite-based methods to identify and quantify DNA methylation are the current gold standard, their usage has some caveats. Bisulfite conversion itself introduces a range of systematic sequencing biases by DNA degradation. For example, DNA degradation induced by bisulfite conversion depletes more regions with unmethylated cytosines, while incomplete conversion can lead to overestimation of methylated cytosines. On top of these, methylation status of specific CpG-rich regions may cause their under- or over-estimation in WGBS experiments. These biases are even more pronounced during library amplification step (Olova *et al.*, 2017).

If single base resolution is not required, several other 5hmC detection methods could be considered: antibody immunoprecipitation (h)MeDIP-seq (Bock *et al.*, 2010); or selective labelling and pulldown (e.g., hMe-Seal) (Han *et al.*, 2016; Song *et al.*, 2012b). Analysis packages such as MeDIPS (Lienhard *et al.*, 2014) provide a suite of tools to analyse (h)MeDIP-seq data including the identification of differentially methylated regions. Although not offering base resolution and lacking sensitivity for regions with low enrichment, antibody immunoprecipitation can enrich for each of DNA modifications with specific antibody, ensuring high specificity at low cost (Tan *et al.*, 2013). Independent of the chosen method it is good practice to validate methylation calls at a locus-specific level with methods such as bisulfite pyrosequencing (Strogantsev *et al.*, 2015).

Analysis

Quality Control and Mapping to the Genome

With all the methods detailed in [Table 1](#), the first step is to map the experimental output to a reference genome. In the case of array based methods, the reported individual probes are mapped to the genome via a lookup table of locations provided by the manufacturer. With second and third generation sequencing methods, the read sequences have to be aligned to a reference genome.

Array methods

Mapping of probes to their genomic locations doesn't require an explicit alignment step as is required with NGS data; instead the probe genomic locations are provided in the manufacturer supplied manifests for the arrays. The quality control steps required for the analysis of the array data is centered around removing poorly performing probes and corrections to batch effects due to bead detection on the chip. There are also control probes on the chip which should be interrogated for a variety of QC metrics. Illumina's Infinium HumanMethylation 450K and MethylationEPIC array chips are based on two distinct probe designs for assaying the methylation status of CpGs requiring normalization to match the differing methylation profiles. Illumina methylation arrays can be analysed using *missMethyl* (Phipson *et al.*, 2015) or *Chip Analysis Methylation Pipeline* (ChAMP) (Morris *et al.*, 2014). Both *missMethyl* and ChAMP R packages accept raw IDAT format files as input and integrate a selection of normalization methods (e.g. SWAN or BMIQ), differential methylation analysis and gene set analysis. Batch effects are corrected using *Combat* (Johnson *et al.*, 2007) in ChAMP and *RUVm* (Maksimovic *et al.*, 2015) in *missMethyl* which is designed to correct unknown source of variation as well as batch effects. ChAMP can additionally identify copy number alterations present in a dataset. Both packages provide the methylation states of the probes passing the QC steps.

Next generation sequencing

Standard steps in BS-seq data analysis are: adapter and sequence trimming, assurance of reads quality, alignment of the reads to the reference genome and methylation calling. We discuss each of these steps in the sections below. [Fig. 2](#) outlines a typical pipeline for the analysis of BS-seq data.

Trimming

Bisulfite conversion itself can introduce biases, as less efficient bisulfite conversion at 5' ends is commonly observed, and this could be misinterpreted as high methylation calls. Also, in any paired-end directional BS-Seq, 5' overhangs created by sonication are

Fig. 2 A typical analysis pipeline for bisulfite based assays for detecting modified cytosine positions. A. Quality control and alignments steps. B. LuxGLM and MOABS are able to perform the required subtraction between different bisulfite based assays to call, e.g., 5hmC. C. Example software for calculating differential methylation between sample groups (e.g., case and control). D. Enrichment for cytosine modifications and histone marks can be performed with programs such as Homer and wiggleTools.

filled with unmodified C during end-repair step in library preparation, which can introduce biases in the genuine methylation state of cytosine at both ends of sequenced reads. Similarly, in RRBS, enzymatic reaction of *MspI* also creates 5' overhangs, and the missing positions are filled with unmodified C, but not of the true genomic cytosine. Additional consideration is also required for the sequencing of Post-Bisulfite Adapter Tagging (PBAT) libraries. Random priming step can introduce biases in base composition and thus in detecting methylation levels, which are affected mostly at the 5' end of all reads. Therefore, it's important to trim affected bases (length of random oligo primers) from the libraries before the alignment step to remove methylation biases. With tools such as Trim Galore! (see Relevant Websites) and Cutadapt (Martin, 2011) all of the biases can be efficiently removed.

Aligners and methylation callers

Mapping of the bisulfite converted reads to a reference genome is challenging due to C to T conversion and therefore reduced sequence complexity. In the course of bisulfite treatment, the top and bottom strands become non-complementary and their PCR amplification products differ, resulting in 4 different sequences: original top (OT), original bottom (OB), complementary top (CT) and complementary bottom (CB) strands. Different aligners approach these issues slightly differently, but arguably the most widely used is Bismark (Krueger and Andrews, 2011). Bismark is considered to be a conservative aligner, with expected alignment rates of around 80% (human), and may be a good choice as its very well supported by the developers. Bismark also has tools to extract methylation calls and distinguishes between the different cytosine contexts: CpG, CHH and CGH. methylKit can perform the methylation calls directly from aligned BAM files as well as import methylation calls from Bismark (Akalın et al., 2012). This is particularly convenient for creating pipelines as methylKit is primarily utilised for differential methylation analysis (see Section Differential Methylation). Alternatively, BWA-Meth offers more lenient aligning with rates (e.g., upwards of 90% (human) as it performs soft-clipping). This tool can be very useful if investigating genomic variants and may allow more reads to be aligned, but also some reads may be incorrectly mapped to genomic regions like repetitive regions.

The presence of SNPs can contribute to the miscalling of cytosine modifications, especially through C to T substitutions. Therefore, knowing the positions of common SNPs, for example, from dbSNP (Sherry et al., 2001), can be utilised to mask these positions in SNP aware alignment/calling software such as Bis-SNP (Liu et al., 2012).

In order for 5hmC, 5fC and 5caC to be accurately called in bisulfite based sequencing, there is a requirement for high read coverage to separate the true methylation signal from background noise (Discussed below). The high cost of sequencing to achieve the required coverage can be ameliorated with tools such as BSmooth (Hansen et al., 2012). BSmooth provides an entire pipeline from the raw reads, through alignment to differential methylation calling. However, the feature of particular interest is the smoothing of the methylation signal across regions to improve the precision of calling the methylation status of cytosine modifications. In this way, low coverage regions can be included in the differential methylation calling, where they may have been excluded in Fisher's Exact test based methods (Discussed below).

Spike in controls

It is important to monitor conversion rates of the bisulfite and oxidation reactions to ensure they are within recommended limits. Deviations from these limits will have a significant negative impact during the downstream calling of the cytosine modifications. Spike-in-controls can be artificial sequences or from a different species to the samples, and are added prior to bisulfite conversion to assay the efficiency of conversion in analysed samples. As the sequence of the spike-in-controls are known they can be aligned to a control reference and analysed in a similar manner to the sample sequences. The absolute quantification of spike-in-controls may also prove even more valuable in circumstances when global changes in methylation occur ([Hardwick et al., 2017](#)). In addition to the usage of spike-in-controls, methylation callers should also provide reports including the proportions of cytosine and methylated cytosines in the aligned reads.

Determining the Cytosine Modification Proportions

Once a sample's detectable cytosines have been mapped to the genome, regardless of the bisulfite- or enzyme-based assay used, in order to determine the relative proportions of the assayed cytosine modifications, subtractions must be performed. For example, to infer the 5hmC level at a specific cytosine, the number of methylated cytosines in a pileup from oxBS (5mC) must be subtracted from BS (5mC & 5hmC) ([Table 2](#)). Inherent in the subtraction of data is the accumulation of noise from the separate assays. Great care must be taken to perform read filtering and apply statistical tests to minimize the effect of the noise which can lead to biologically meaningless negative values.

The original publications for the single-base resolution sequencing of 5hmC used a minimum read coverage filter for CpG sites and for statistical significance of the difference between the bisulfite and oxidation results; Benjamini-Hochberg and Fisher's tests were used ([Booth et al., 2014, 2013, 2012](#)). A further recommendation was to pool CpG sites from within CpG Islands where five or more CpG site methylation values did not vary more than 20% for 5mC and 10% for 5hmC. The pooling of the CpG sites reduces the high coverage requirements for calling cytosine modifications at single CpG positions. Coverage of over 500 reads would be required to reliably detect below 5% hmC, where pooling enables detection of hmC down to 1% ([Booth et al., 2013](#)). This protocol, which we refer to as the Booth method, for read coverage and statistical testing should be considered the minimum requirement for performing a subtraction and is applicable to both array and NGS approaches.

Methylation arrays

The analysis results from MissMethyl and ChAMP, as detailed above, provide the methylation status of each of the assayed CpG site on the array. However, neither method performs the subtractions required to call the proportions of 5hmC, 5fC or 5caC modifications. To address this, two related methods were developed for the validation of the compatibility of the oxBS treatment on the 450K array ([Field et al., 2015; Stewart et al., 2015](#)). Subtractions between BS and oxBS to call 5hmC are performed for CpG sites with a methylation difference over a threshold ($\Delta\beta > 0.3$). This filtering has the effect of minimizing the number of negative values in a similar manner to the Booth approach for NGS. A more recent package, OxyBS ([Houseman et al., 2016](#)), utilises maximum likelihood estimates to call 5hmC from matched BS and oxBS samples. This method goes beyond naïve threshold filtering by modelling the methylation states (5C, 5mC, 5hmC) in the BS and oxBS paired samples.

Next-generation sequencing

There are several tools available for performing the subtractions required to make 5hmC calls ([Table 2](#)). MLML ([Qu et al., 2013](#)) is one of the earliest methods for estimating 5mC and 5hmC levels and has been developed for BS/oxBS, TAB-Seq and a combination of BS/oxBS and TAB-Seq. Maximum likelihood estimates are used to model the methylation states, and at sites with negative values the latent variables are used to approximate the MLE. oxBS-MLE ([Xu et al., 2016](#)) uses binomial modelling of paired BS and oxBS samples and is applicable to both array and sequencing methods. The method is related to OxyBS, but overcomes the CPU time constraints enabling studies to be performed on much larger sample sizes. MOABS ([Sun et al., 2014](#)) was

Table 2 Comparison table of a selection of subtraction methods for calling cytosine modifications. A variety of modelling approaches are used: Maximum Likelihood Estimates (MLE), Hidden Markov Models (HMM), General Linear Models (GLM). None of the methods have been applied and published for 5fC, and 5caC, however, they should be in theory, with optimizations applicable

	Statistical significance	Negative value filtering/modelling	Utilises biological replicates	Array/NGS/Both	5mC/5hmC/5fC/5caC/All
Booth Methods	Y	Filtering	No	NGS	All
OxBS-Array	Y	Filtering	No	Array	5mC/5hmC
Oxy-BS	Y	Modelling (MLE)	No	Array	5mC/5hmC
oxBS-MLE	Y	Modelling (MLE)	No	Both	5mC/5hmC
MLML	Y	Modelling (MLE)	No	Both	5mC/5hmC
MOABS	Y	Modelling (Beta-binomial)	Yes	NGS	5mC/5hmC
H(O)TA	Y	Modelling (hMM)	Time points	NGS	5mC/5hmC
LuxGLM	Y	Modelling (GLM)	Yes	NGS	All

primarily designed to improve the calling of 5mC sites in traditional bisulfite sequencing, however an extension to the beta-binomial method permits 5hmC calling. MOABS also takes into account biological replicates in methylation calls to account for biological variation. H(O)TA (Kyriakopoulos *et al.*, 2017) employs hidden Markov Models (hMM) of the methylation states of the cytosines in BS and oxBS paired samples across experimental time points. LuxGLM (Äijö *et al.*, 2016a,b) is one of the more recently published methods and was designed to work with a variety of chemical and enzymatic treatments followed by sequencing. A general linear model (GLM) is able to capture all cytosine modification methylation states across replicates to estimate the proportions of the modifications assayed.

Differential Methylation

Differentially Methylated Positions (DMPs) or Regions (DMRs) are genomic regions exhibiting distinct methylation states between biological samples, and are thought to have the potential to regulate gene expression. Depending on the samples interrogated, DMRs can be further classified into, e.g., tissue-specific, allele-specific, developmental stage or disease-associated (such as cancer-specific DMRs). Genome wide association studies have shown specific DMRs to be associated with disease states, while locus-specific studies confirmed their functional roles in regulating gene expression. Clear links have been made between DMRs and diseases such as systemic lupus erythematosus, cancer, aging, obesity, inflammatory bowel disease (Baba *et al.*, 2010; Jeffries *et al.*, 2011; McKinney *et al.*, 2015; Soubry *et al.*, 2015; Stirzaker *et al.*, 2016; Venthram *et al.*, 2016). Several DMRs have proved to be valuable epigenetic biomarkers with clinical applications (Barault *et al.*, 2015; Church *et al.*, 2014; Dietrich *et al.*, 2012; Imperiale *et al.*, 2014; Kristensen *et al.*, 2016). Patterns of 5hmC are tissue specific and associate with tissue, organ and developmental stage functionality. For example, in placenta, maternal DNA methylation regulates development of early trophoblast, while unique 5mC and 5hmC patterns of placenta associate with birth weight (Branco *et al.*, 2016; Fogarty *et al.*, 2015; Green *et al.*, 2016; Piyasena *et al.*, 2015; Zhu *et al.*, 2015). The latter example points a valid point how important is to discriminate between 5mC and 5hmC and that bisulfite-seq data (non-discriminative between 5mC and 5hmC) should be treated very carefully.

Determining the locations of the cytosine modifications on the genome is of particular interest in development, however it is often desirable to perform a comparison across conditions. For example, comparisons across tissues, investigating the effect of a gene knockout with CRISPR or in biomarker discovery in a disease case and control. There are a wealth of methods for finding differentially methylated genomic regions. Typically, these require more hands-on tailoring for the most appropriate comparisons in the study in hand and are often supplied as R packages. All the methods highlighted below perform multiple testing correction. BiSeq is designed for RRBS data analysis and performs DMR finding using the Wald statistic from the beta-binomial regression fit R package (Hebestreit *et al.*, 2013). BSmooth searches for bumps on smoothed t-like scores of methylation profiles to find DMRs (Hansen *et al.*, 2012). methylSig is an R package for calling DMRs with likelihood ratio test (and also a beta-binomial approach) (Park *et al.*, 2014). methylKit, an R package, identifies DMRs with logistic regression and Fisher's exact tests (Akalin *et al.*, 2012). methylKit can also directly input methylation calls from Bismark making it suitable for integrating into a pipeline. methylPipe employs Wilcoxon or Kruskal–Wallis paired non-parametric test to identify DMRs and the predicted DMRs can be *in silico* tested for validation with compEpiTools (Kishore *et al.*, 2015).

It is important to state that the identification of DMRs is only a discovery step; further experimental validation is essential. Once a large whole genome case/control study has identified and validated a DMR/biomarker it can be incorporated into a targeted panel to greatly reduce the cost for diagnostic purposes.

Interpretation

Genomic Distribution of Cytosine Modifications

Once the detectable cytosines modifications have been mapped and processed to provide relative proportions of the measurable modifications, it is then desirable to look for where they accumulate in the genome and interpret the biological significance in the context of the experiment being performed. Genome tracks such as RefSeq genes (intron/exon), promoters, enhancers, repeats (inc Alu LINE elements), CpG Islands, Shores, Shelves can be downloaded in BED format from the UCSC Genome Browser (Raney *et al.*, 2014). Tools such as bedTools2 can then be used to perform intersections with the elements of choice to address specific biological questions such as: are 5hmC sites enriched in promoters as compared to enhancers? (Quinlan and Hall, 2010).

Correlation With ChIP-Seq

Chromatin immunoprecipitation followed by high throughput sequencing (ChIP-seq) provides genomic locations of histone marks such as H3K4me3 found in promoters under active transcription and H3K27ac marking active over poised enhancers. Studies performing methylation sequencing are often coupled with ChIP-Seq for the specific tissue or cell type of interest (Guo *et al.*, 2017). In order to determine the co-localization of cytosine modifications with the histone marks tools such as wiggleTools (Zerbino *et al.*, 2014), Homer (Heinz *et al.*, 2010), bedTools2 (Quinlan and Hall, 2010), and GIGGLE (Layer *et al.*, 2017) can be used.

Correlation With RNA-Seq

DNA methylation analysis alone may be difficult to interpret, as DNA modifications can exert different effects depending on their position relative to the genes. To make a compelling case for the role of the assayed cytosine modifications on gene expression, it is recommended to perform a matched sample RNA-Seq experiment. Bulk RNA-Seq or transcription start site (TSS) specific CAGE-Seq enable the effect on gene expression in differentially methylated regions to be quantified (Steyaert *et al.*, 2016). The integrative transcriptional-epigenomic studies and their bioinformatics analyses are far more challenging in the single-cell approaches, but promising methods are under development (Angermueller *et al.*, 2016; Clark *et al.*, 2016; Hu *et al.*, 2016).

Allelic Expression

Not all genes are expressed from both alleles. Some genes are expressed in a parent-of-origin specific manner and do not follow classical Mendelian inheritance. These are known as imprinted genes and since both active and repressed copies of imprinted genes can co-exist in the same nucleus, they are particularly suited as a model system to study epigenetic gene regulation. Imprinted genes have been shown to play a role in the growth of the placenta and the development of the embryo, as well as having postnatal behavioral and physiological functions (Frost and Moore, 2010; Garfield *et al.*, 2011; Li *et al.*, 1999).

As imprinted genes are expressed from one allele, they are more susceptible to mutations and dysregulation, coinciding with their abnormal expression in diseases and cancer. A common feature found in imprinted gene clusters are imprinting control regions (ICRs) that are differentially methylated on both alleles (and so they are differentially methylated regions, DMRs). Parent of origin specific methylation is established in germline and contributes to allele specific expression of imprinted genes. Also, some loci exhibit non-imprinted allelic methylation that occurs at random. This phenomenon can be partially explained by existence of SNPs with CpGs (Rouhi *et al.*, 2006; Shoemaker *et al.*, 2010; Strogantsev *et al.*, 2015). To computationally determine the parental origin of an allele, the reads must be aligned to the genome of each parent. In human samples, genotyping permits the parental origin of the allele to be resolved. It is also possible to use triploidies to take advantage of parental genomic contributions (Yuen *et al.*, 2011). In mouse, the use of hybrid crosses allows the parental origin of the gene of interest to be resolved (Kobayashi *et al.*, 2009).

Discussion

In this article, competing methods for assaying DNA modifications were reviewed, many of which are able to assay cytosine modifications at single base resolution. However, there are limitations to the current methods, such as the requirement for chemical or enzymatic treatments, PCR amplification and high depth sequencing, all requiring computational tools to account for these sources of deviation from the true biological signal.

In mammals, cytosine modifications are predominantly found at CpG sites, and often clustered in CpG islands. These regions are therefore of low complexity due to the enrichment of CpG sites making the unique mapping of short-reads difficult, or impossible, leaving gaps in assaying the methylome. To cover these gaps, new sequencing technologies such as long-read sequencing (see Section Future Directions) are required, and accompanying bioinformatics tools to assay the nucleotide modifications need to be developed. Tool development will be key to unlocking these previously un-mappable regions of genomes.

Importantly, cytosine modifications at single base resolution need to be carefully interpreted, ideally with orthogonal methods such as ChIP-Seq or RNA-Seq, as well as with allelic expression. Together, they make powerful tools to dissect roles of DNA modifications in epigenetic regulation of gene expression.

Future Directions

Emerging technologies, such as the long-read sequencing technologies, are rapidly approaching the accuracy of the short-read based methods for methylation sequencing. A further development expected over the next few years is the ability to detect all cytosine modifications within single cells. Methods have recently been developed to assay 5mC in single cells and further developments have permitted the simultaneous sequencing the methylome and transcriptome from the same cell.

Long-Read Sequencing

Cytosines undergoing modifications are often located in clusters (e.g., CpG islands) which are therefore repetitive in nature. Short-read based methods are unable to uniquely map short reads to repetitive regions, resulting in the under representation of these important regions. Long-read based methods such as Pacific Biosciences single-molecule real-time sequencing (SMRT) and Oxford Nanopore do not suffer from this limitation as the reads can be 10's or 100's of kilobases in length and can therefore span and uniquely map to these CpG dense regions. A further key advantage is the ability to directly assess the methylation status of cytosines without the need for treatments such as bisulfite, or enzymatic modification. SMRT sequencing measures the

incorporation of nucleotides in real time and is able to distinguish between each of the modification states of cytosine and adenine (Fang *et al.*, 2012; Suzuki *et al.*, 2015), while Nanopore technology detects DNA bases, including modified cytosines, by measuring electrostatic charge as a DNA strand passes through a protein nanopore (Rand *et al.*, 2017; Simpson *et al.*, 2017). The challenge now is to develop new bioinformatics methods for long-read sequencing such as high accuracy base calling of methylated bases

Single Cell Sequencing

Methods have been developed to assay 5mC in single cells using bisulfite treatments (Smallwood *et al.*, 2014). However, to date, only TAB-Seq is able to assay 5hmC in single cell treatments as the bisulfite methods are too harsh and unable to achieve the required read depths for the subtractions (Clark *et al.*, 2016). More recent methods, e.g., G&T-Seq, have been developed to simultaneously sequence the genome and transcriptome (Macaulay *et al.*, 2015). In the future, it will hopefully be possible to simultaneously assay all the levels of epigenetic detail of a single cell such as cytosine modifications, histone marks, chromatin structure and 3D genome arrangements in combination with the transcriptome, genome and proteome (Clark *et al.*, 2016). As with long-read sequencing methods the challenge for the bioinformatics community is to develop new multi-modal methods to simultaneously analyse the multi-ome data sets derived from single cells.

Closing Remarks

The current state-of-the-art methods for interrogating cytosine modifications rely on chemical or enzymatic treatments accompanied with PCR amplification. Future gold standard methods will undoubtedly forgo these treatments and directly infer the methylation status of DNA and RNA nucleotides from the native molecules. The current, and future methods, will continue to further our understanding of the biological role of nucleotide modifications and their impact in human disease. Perhaps, most excitingly, these modification marks could be edited with systems such as CRISPR-CAS9 to treat a wide range of diseases.

Biographical Sketch

Malwina Prater is a bioinformatician at the Centre for Trophoblast Research, University of Cambridge. Her previous work at Cambridge Epigenetix (CEGX) involved developing technologies that enable accurate quantification of methylcytosine (mC) and hydroxymethylcytosine (hmC) at a single base resolution. Prior to this, she was undertaking her PhD at Cancer Research UK Cambridge Institute, University of Cambridge. Her work focused on long non-coding RNAs and epigenetic regulation of gene expression. She has also been involved in projects investigating control of protein expression in yeast (University of Edinburgh) and ribosome biogenesis in plants (Goethe University in Frankfurt).

Russell Hamilton heads the bioinformatics core facility at the Centre for Trophoblast Research (CTR), University of Cambridge. The focus of the CTR is the study of the placenta and maternal-fetal interactions during pregnancy and brings together over 25 Principal Investigators based in different departments within the University of Cambridge and Babraham Institute. He has previously worked in industry at Cambridge Epigenetix (CEGX) developing epigenetics tools to enable single base resolution sequencing of methylcytosine (mC) and hydroxymethylcytosine (hmC). Prior to this was a senior postdoc in the Department of Biochemistry at University of Oxford, working on the RNA structural motifs required for mRNA localization and their interaction with trans-acting protein factors. Russell received an MSc in Intelligent Systems from the University of Aberdeen and his PhD in bioinformatics from the University of Edinburgh. At each of his previous positions, Russell has set up bioinformatics infrastructure including pipelines for next-generation sequencing, RNA structure searches, protein structural modelling and a microscope imaging facility.

Introduction

The analysis of epigenomic data often involves the comparison with other epigenomic data. For example, consider the analysis of DNA methylation data where a certain genomic locus is detected to have a methylation level lower than its flanking regions. Such a locus is regarded as a candidate of cis-regulatory elements. However, further insights into its regulatory role are difficult to obtain solely from DNA methylation data. In such cases, it is useful to compare DNA methylation data with histone modification data. If the locus has H3K4me3, it is inferred as a promoter that regulates the expression of neighboring genes. Alternatively, the locus may have H3K4me1, suggesting that it is an enhancer regulating the expression of distal genes. Epigenomic data can also be compared between different cell types. For example, consider that the DNA methylation data were collected from stem cells, and are compared with those from differentiated cells. If the locus shows an increased methylation level in the differentiated cells, its function is predicted to be related to the differentiation from the stem cells. These examples clearly demonstrate that the comparison of epigenomic data is a powerful approach in epigenome research.

This article aims to describe conventional methods for comparing epigenomic data. We show practical issues that arise in real-life analysis settings, and explain how to address these problems. A review of widely-used software for various kinds of epigenomic data is provided. We also provide a review of public epigenomic databases that can be used as a reference for the comparison with in-house epigenomic data. Finally, we present a case study where mesenchymal stem cells and mature fat cells are compared using DNA methylation, histone modification, transcription factor binding, and gene expression data. The study provides an example of how to combine each analysis task in constructing the whole analysis for addressing a specific research question.

Background

Epigenetic Modification

The knowledge on epigenetic modification is necessary to interpret the results of epigenomic data analysis. [Table 1](#) summarizes representative epigenetic modifications and their known functions in gene regulation.

Table 1 Epigenetic modifications and their functions in gene regulation

Epigenetic modification	Indication	Experimental technology
H3K4me3	Promoter	ChIP-seq
H3K4me1	Enhancer	
H3K27ac	Activated	
H3K9me3	Heterochromatin	
H3K27me3	Repressed	Bisulfite-seq, Infinium BeadChip
H3K36me3	Active gene body	
DNA methylation, promoter	Repressed	
DNA methylation, gene body	Activated (in some cell types)	

Several kinds of histone modification have established regulatory roles. H3K4me3 and H3K4me1 are histone modifications that indicate promoters and enhancers, respectively. H3K27ac is a hallmark of active chromatin. Genomic loci that harbor both H3K4me1 and H3K27ac are called active enhancers, suggesting that genes regulated by these enhancers are activated. On the other hand, genomic loci that have H3K4me1 but lack H3K27ac are sometimes called “primed” enhancers, meaning that these loci have the potential to function as enhancers although their target genes are still not activated in the cell type of interest. H3K9me3 and H3K27me3 are hallmarks of repressed chromatin. H3K9me3 tends to be observed at heterochromatic regions consistently repressed in a broad range of cell types, while H3K27me3 indicates a temporal repression in specific cell types. As a last example, H3K36me3 is observed at actively transcribed gene bodies.

The function of DNA methylation is more complicated and context-dependent in comparison to histone modification. In general, DNA methylation is considered to modulate the binding affinity of transcription factors either positively or negatively, and its regulatory outcome depends on the function of transcription factors such as activators or repressors. For example, if a transcription factor with an activator function preferentially binds to unmethylated DNA, an increase in DNA methylation will decrease the transcription factor's affinity for that region, thereby repressing gene expression. Despite this complexity, some genome-wide associations are known between DNA methylation and gene expression. DNA methylation at promoters is associated with the repression of gene expression. Inversely, DNA methylation at gene bodies is associated with the activation of gene expression in some cell types.

There are many other kinds of epigenetic modification not included in [Table 1](#). For histone modification, there are a variety of “non-standard” modifications such as phosphorylation, ubiquitination, and sumoylation. See [Zentner and Henikoff \(2013\)](#) for a recent review. While DNA methylation usually refers to cytosine methylation in the CpG context (cytosines followed by guanines), other kinds of DNA methylation are known to be important in some cell types and/or organisms. These include cytosine methylation in the non-CpG context ([Jang et al., 2017](#)) and hydroxymethylation ([Guibert and Weber, 2013](#)). In addition, it is important to be aware that the current knowledge on epigenetic modification has mainly been obtained from studies on model organisms such as mammals and yeasts. Therefore, one should be careful when analyzing epigenomic data from non-model organisms where epigenetic modifications may have unknown functions.

It is common to incorporate transcription factor binding data into epigenomic data analysis even though they are not strictly considered to be epigenomic data. This is because transcription factor binding and epigenetic modification are closely related to each other. For example, the binding affinity of some transcription factors is known to be modulated by DNA methylation, and some transcription factors are known to induce histone modification at the binding sites. Gene expression data are also regularly utilized in epigenomic data analysis. Since a major function of epigenetic modification is gene regulation, gene expression data are useful to analyze the regulatory outcome of epigenetic modification in the cell type of interest.

Experimental Technology and Raw Data Processing

The understanding of experimental technologies for measuring epigenomic data is a prerequisite for selecting the appropriate methods for analyzing the data. [Table 1](#) includes experimental technologies used for various epigenetic modifications. Most kinds of epigenomic data are measured by next-generation sequencing (NGS) or microarray-based technologies. Histone modification and transcription factor binding are measured by chromatin-immunoprecipitation sequencing (ChIP-seq) where DNA fragments bound by a specific protein are extracted by an antibody prior to sequencing. DNA methylation is measured by bisulfite sequencing (bisulfite-seq) where unmethylated cytosines are chemically converted and sequenced as thymines. DNA methylation can also be measured by a microarray-based technology called Illumina Infinium BeadChip. Gene expression is measured either by NGS (RNA-seq) or microarrays.

Raw data generated by these experimental technologies are fastq files for NGS, and platform-dependent files for microarrays (e.g., tab-delimited text files for Agilent microarrays, and CEL files for Affymetrix microarrays). With appropriate data processing, they can be transformed into signal values along genomic positions. For example, DNA methylation data are represented as a methylation level (also referred to as a methylation ratio, a methylation rate, or a beta value) for each cytosine position, which is a value ranging from 0 to 1 that indicates the fraction of methylated cytosines in a cell population. Similarly, gene expression data are represented as an expression level for each gene that is linked to its genomic position. In this article, we focus our discussion on the comparison of epigenomic data, assuming that input data are already represented as signal values. Therefore, the detail in raw data processing such as read mapping falls outside the scope of this article. However, it is still important to be aware of the experimental technology used for measuring the epigenomic data since some downstream analyses need care depending on different experimental technologies. For example, conventional methods for the detection of differentially expressed genes (DEGs) are different for RNA-seq and microarray data. In such cases, we explain the analyses separately for each experimental technology.

Application

In this section, we first describe practical issues in the comparative analysis of epigenomic data. Then, we provide a review of widely-used software for each kind of epigenomic data (The list of all software discussed in this article is given in Appendix). Finally, we provide a review of public epigenomic databases.

Comparative Analysis: Correlation and Difference

A useful method for comparing epigenomic data is to evaluate the correlation between two epigenomic datasets. For example, consider two DNA methylation datasets, each of which represents methylation levels measured from a certain cell type. The correlation coefficient between the methylation levels can be used as a similarity measure between the two cell types.

Another method for the comparative analysis is to detect differences between two epigenomic datasets at specific genomic loci. For example, one can calculate the difference in methylation levels between two cell types at each cytosine position. Cytosines with large differences in methylation levels are called differentially methylated cytosines (DMCs). Methylation differences can be detected not only for a cytosine position but also for a window of a certain length using methylation levels averaged over the region. In such cases, detected regions are called differentially methylated regions (DMRs).

Defining Windows

As shown in the above example of DNA methylation, signal values computed from epigenomic data are often averaged or summed over the windows of genomic regions. Therefore, how windows are defined is an important practical issue. The most general method for defining windows is a sliding-window approach where windows are defined as fixed-length regions (e.g., 1000 bp) with a certain step size (e.g., 500 bp). Another conventional method is to define windows based on their positions relative to genes. For example, fixed-length windows around transcription start sites (TSSs) are often used for analyzing promoters. Windows are sometimes defined using other genomic elements (e.g., retrotransposons) to specifically analyze their epigenomic profiles.

Windows can also be defined using epigenomic data themselves. Some tools are designed to detect DMRs without pre-specifying regions of interest by determining the boundaries of DMRs solely from DNA methylation data. Detected DMRs can be used as windows for analyzing other kinds of epigenomic data such as transcription factor binding. Similarly, one can detect transcription factor binding sites from ChIP-seq data, and use these sites as windows for analyzing DNA methylation.

Biological Replicates

Biological replicates refer to parallel measurements of biologically distinct samples produced from the same experimental condition. It is well known that the comparative analysis of omics data becomes more accurate and reproducible by using replicates. A simple method for utilizing replicates is to average signal values from individual replicates. However, this method fails to incorporate the information of variance among replicates. Most tools for detecting DEGs utilize the variance information for evaluating a statistical significance (i.e., p-value). For DMC and DMR detection, some tools support replicates for evaluating p-values while others do not.

Biological replicates should be distinguished from technical replicates that refer to repeated measurements from the same biological sample. While averaging technical replicates can reduce the experimental noise of measurements, their variance information is not effective to increase the power of statistical testing. This is because the variance among technical replicates does not represent biological variation. See [Blainey et al. \(2014\)](#) for a detailed discussion on handling biological and technical replicates.

Although replicates are useful, their availability is sometimes limited in real-life analysis settings. This is especially true for epigenomic data measured by newer technologies with higher experimental costs. For example, while replicates are quite common for microarrays, they are relatively limited for DNA methylation data measured by bisulfite-seq (e.g., few or no replicates are available). In such cases, one needs to resort to replicate-free analysis where the difference in methylation levels between single samples is used for detecting DMCs and DMRs.

DNA Methylation

Raw data processing of bisulfite-seq is performed by software such as Bismark ([Krueger and Andrews, 2011](#)), BSMAP ([Xi and Li, 2009](#)), and Bisulfighter ([Saito et al., 2014](#)). These tools map bisulfite-seq reads to a reference genome, and calculate a methylation level for each cytosine position based on the mapping results. The detection of DMCs and DMRs is conducted with software such as BSmooth ([Hansen et al., 2012](#)) and ComMet ([Saito and Mituyama, 2015](#)). These tools are capable of *de novo* DMR detection without pre-specifying windows. BSmooth supports replicate-aware analysis but is not applicable to data without replicates, while ComMet supports replicate-free analysis but cannot utilize replicate information. We refer to the review ([Tsuji and Weng, 2016](#)) for other tools available for bisulfite-seq data.

Raw data processing of Infinium BeadChip is performed by software such as IMA ([Wang et al., 2012](#)) and Minfi ([Aryee et al., 2014](#)). These tools compute methylation levels at individual cytosine positions (often referred to as beta values), and average methylation levels for various gene-related windows including promoters and gene bodies. The detection of differential methylation for Infinium BeadChip is usually conducted with these windows using methods originally developed for gene expression microarrays. For example, IMA detects DMCs and DMRs using the limma method ([Ritchie et al., 2015](#)) developed for detecting DEGs. DMR detection without pre-specified windows is not common for Infinium BeadChip data, perhaps due to a limited number of measurable cytosine positions, although some tools are developed for this purpose ([Morris et al., 2014](#)). See the review ([Dedeurwaerder et al., 2014](#)) for other Infinium BeadChip data analysis tools.

DNA methylation data are commonly compared with gene expression data. Since DNA methylation at promoters is associated with gene repression, the inverse correlation between methylation levels and expression levels are used in many studies. Similarly,

DMCs and DMRs between cell types can be compared with DEGs. However, it is important to be aware that the association between DNA methylation and gene expression is evident but not so strong. Therefore, it is often the case that one fails to detect an inverse correlation between methylation levels and expression levels. A practical tip here is to focus on the top-ranked genes. For example, the comparison of methylation levels between the top 10% of genes with the highest expression levels and the bottom 10% of genes with the lowest expression levels will result in a clear difference between the two groups. A similar issue also applies when comparing DMCs and DMRs with DEGs between different cell types.

Histone Modification and Transcription Factor Binding

Read mapping for ChIP-seq is performed by software such as Bowtie (Langmead *et al.*, 2009) and BWA (Li and Durbin, 2009). Signal values for ChIP-seq data are the fraction of mapped read counts in the ChIP sample (i.e., immunoprecipitated by an antibody) divided by those in the input sample (i.e., sequenced without immunoprecipitation). This task is conducted by software such as MACS (Zhang *et al.*, 2008), SICER (Zang *et al.*, 2009), and DROMPA (Nakato *et al.*, 2013). Other tools for ChIP-seq data are reviewed in Nakato and Shirahige (2017).

An important task in ChIP-seq data analysis is peak detection where genomic regions enriched with signal values are determined by comparing read mapping results between ChIP samples and input samples. The above tools for computing signal values also support peak detection. However, it is worth noting that peak detection is a difficult task, and it is often the case that peaks detected by different tools show a strong disagreement in their numbers and positions. This is partly because the characteristics of peaks are different for various DNA-binding proteins: some proteins produce sharp peaks with signal values highly enriched in short regions, while others produce broad peaks showing an intermediate enrichment throughout long regions. Due to this difficulty, signal values are sometimes directly used for downstream analyses without peak detection. Nonetheless, peaks are useful as windows for comparing ChIP-seq data with other epigenomic data.

Histone modification data are frequently compared with DNA methylation data. For example, one can calculate the methylation levels at H3K4me1 peaks for measuring their enhancer activity. Similarly, methylation levels at transcription factor peaks are used for surveying the interplay between transcription factor binding and DNA methylation. The detection of DMRs can also be conducted using ChIP-seq peaks as windows. Since peak detection involves the technical difficulties as explained above, sliding windows are also used instead of peaks. For this purpose, sliding windows with the highest enrichment of ChIP signals (e.g., the top 10%) are used for calculating methylation levels.

Gene Expression

Read mapping for RNA-seq is performed by software such as TopHat2 (Kim *et al.*, 2013) and STAR (Dobin *et al.*, 2013). Expression levels are measured as fragments per kilobase million (FPKM) computed by Cufflinks (Trapnell *et al.*, 2010), or transcripts per million (TPM) computed by RSEM (Li and Dewey, 2011). DEGs can be detected by tools like Cuffdiff (Trapnell *et al.*, 2013), edgeR (Robinson *et al.*, 2010) and DEGseq (Wang *et al.*, 2010), all of which support replicates. Compared to bisulfite-seq and ChIP-seq data, there are numerous tools available for RNA-seq data. See Conesa *et al.* (2016) for the recent review.

Raw data processing of gene expression microarrays is performed by software such as limma (Ritchie *et al.*, 2015) and affy (Gautier *et al.*, 2004). limma supports various types of microarrays produced by Agilent, while affy is a widely-used package for Affymetrix microarrays. limma is also a conventional tool for detecting DEGs with support for replicates.

Gene expression data are used in epigenomic data analysis for evaluating the regulatory outcome of epigenetic modification. For example, when a genomic locus is detected as an enhancer candidate with a high H3K4me1 signal and a low DNA methylation level, its influence on gene expression can be evaluated by RNA-seq or microarray data.

Chromatin State Estimation

One of the goals of epigenomic data analysis is to annotate genomic loci with some “chromatin states”. For example, one can annotate loci with high H3K9me3 signals and DNA methylation levels as the “heterochromatin state”, and loci with high H3K4me1 and H3K27ac signals accompanied by low DNA methylation levels as the “active enhancer state”. Chromatin state estimation is a task for doing such annotations by integrating various kinds of epigenomic data. ChromHMM (Ernst and Kellis, 2012) is a software that is commonly used for chromatin state estimation.

Public Databases

It is effective to incorporate public epigenomic data into the analysis of in-house epigenomic data. For example, even if you only have DNA methylation data, you may find histone modification data measured from the same cell type in public databases, allowing the comparative analysis between the datasets. Epigenomic data published in previous studies are deposited in the Gene Expression Omnibus (GEO) database where raw NGS data (fastq files) can be found by following a hyperlink to the Sequence Read Archive (SRA) database. In practice, it is important to be aware that the word search functionality in GEO and SRA sometimes fails to retrieve relevant data. Thus, it is highly recommended that general search engines (e.g., Google) are used in combination

with GEO and SRA. In addition, it is useful to visit the web portals of international epigenome projects, including International Human Epigenome Consortium (IHEC), Encyclopedia of DNA Elements (ENCODE), Roadmap Epigenomics, and BLUEPRINT Epigenome. These web portals organize various kinds of epigenomic data as a form of the “experiment matrix” where rows and columns represent cell types (e.g., embryonic stem cells) and experimental technologies (e.g., bisulfite-seq), respectively, so that one can easily find epigenomic data of their interest. The URLs of these databases and web portals are given in Relevant Websites.

Case Study

In the previous sections, many tasks in the comparative analysis of epigenomic data were explained separately. In practice, however, these tasks need to be combined for addressing a specific research question. Here, we show such an example using a case study. The study is the re-analysis of the data from [Takada *et al.* \(2014\)](#) where human adipose-derived stem cells (ADSCs) are compared to mature fat cells differentiated from ADSCs (FatCs) based on various types of epigenomic data. The purpose of the study is to find epigenetic markers that characterize the differentiation from ADSCs to FatCs.

Data

For ADSCs and FatCs, DNA methylation and gene expression data were measured by bisulfite-seq and RNA-seq, respectively. These were in-house data produced by the authors of the original study, and deposited in the SRA database with the accession number SRP003529. The authors also used histone modification and transcription factor binding data from FatCs. These were public data measured by ChIP-seq, and were downloaded from the SRA database with the accession number SRP002343. Replicates were not available for these datasets. For bisulfite-seq data, read mapping and the calculation of methylation levels were performed by Bisulfighter ([Saito *et al.*, 2014](#)). Read mapping for RNA-seq data was performed by TopHat2 ([Kim *et al.*, 2013](#)), and expression levels (FPKM) were calculated by Cufflinks ([Trapnell *et al.*, 2010](#)). Read mapping for ChIP-seq data was conducted by Bowtie ([Langmead *et al.*, 2009](#)), and peaks were detected by MACS ([Zhang *et al.*, 2008](#)).

Comparison of DNA Methylation and Gene Expression

We first compared DNA methylation with gene expression in ADSCs. The methylation levels of promoters and gene bodies were calculated for all genes. Promoter windows were defined as regions around the TSSs from -1000 bp upstream to $+500$ bp downstream, while gene body windows were defined as regions from $+2000$ bp downstream of the TSSs to the corresponding transcription termination sites. We then compared FPKM between the top 10% of genes with the highest methylation levels, and the bottom 10% of genes with the lowest methylation levels ([Fig. 1](#)). As expected, genes with highly methylated promoters tended to have low FPKM values, while genes with highly methylated gene bodies tended to have high FPKM values.

Fig. 1 Comparison of expression levels between the genes with the highest and the lowest methylation levels in ADSCs. Expression levels (FPKM) were compared for all genes, the top 10% of genes with the highest methylation levels, and the bottom 10% of genes with the lowest methylation levels. The analysis was conducted separately for promoter methylation and gene body methylation. *: $P < 1e-100$ (Mann-Whitney U test).

Comparison of DNA Methylation Between Cell Types

We next compared DNA methylation between ADSCs and FatCs using promoter methylation levels. Only small differences in promoter methylation levels were observed between ADSCs and FatCs (**Fig. 2**). For reference, when a similar analysis was conducted between ADSCs and induced pluripotent stem cells (iPSCs), promoter methylation levels were more diverse. This was surprising because when we compared gene expression using FPKM, similar levels of correlation were detected for the two comparisons (Pearson correlation coefficients: 0.79 for ADSCs versus FatCs, and 0.88 for ADSCs versus iPSCs). These results suggest that differential methylation between ADSCs and FatCs occurs at specific genomic loci other than promoters.

Comparison of DNA Methylation at Transcription Factor Binding Sites

To find specific loci harboring differential methylation between ADSCs and FatCs, we used ChIP-seq data for PPAR γ , a transcription factor known to function as a master regulator of fat cell differentiation. PPAR γ peaks were detected in FatCs, and then these peaks were used as windows for differential methylation analysis between ADSCs and FatCs. Interestingly, specific hypomethylation was found at PPAR γ peaks (**Fig. 3**). A similar analysis was also conducted using ChIP-seq data for H3K4me3 that indicates general promoters, but the hypomethylation was not observed. Therefore, these results demonstrated that specific hypomethylation at PPAR γ binding sites represents epigenetic markers for fat cell differentiation.

Fig. 2 Comparison of DNA methylation between cell types. Two-dimensional density plot where brighter colors indicate larger numbers of promoters with corresponding methylation levels. (Left) Promoter methylation levels were compared between ADSCs and FatCs. (Right) A similar analysis was conducted between ADSCs and iPSCs.

Fig. 3 Comparison of DNA methylation in light of transcription factor binding and histone modification. Two-dimensional density plot similar to **Fig. 2**. (Left) Methylation levels at PPAR γ peaks. The bright colors in the bottom-right of the plot region indicate the hypomethylation of PPAR γ binding sites in FatCs compared to ADSCs. (Right) Methylation levels at H3K4me3 peaks. Hypomethylation was not observed.

Discussion

The comparative analysis of epigenomic data involves several practical issues including how to define windows and how to handle biological replicates. As for replicates, some tools do not support replicates, especially for epigenomic data from relatively new experimental technologies. However, there is a general framework called IDR (Li *et al.*, 2011) that can extend replicate-free methods to replicate-aware versions. Indeed, IDR is extensively used for ChIP-seq data in the ENCODE project where peaks detected from individual replicates are integrated so that reliable peaks showing an agreement among all replicates are retained in the final result.

Another practical issue yet to be addressed in this article is the problem of batch effects. Batch effects refer to the difference detected between data due to artifacts such as those introduced from the laboratory environments (e.g., the difference in the dates of experiments, and/or the difference in the persons who conducted experiments). Batch effects are problematic because they may cover up true biological differences between epigenomic data. ComBat (Johnson *et al.*, 2007) and SVA (Leek and Storey, 2007) are widely-used methods for the detection and the correction of batch effects. The consideration of batch effects is necessary not only for the comparison between in-house and public data but also for the comparison of in-house data measured in different laboratory environments.

Future Directions

The advent of new experimental technologies provides new kinds of epigenomic data. An important example of new epigenomic data is three-dimensional genome structures measured by high-throughput chromosome conformation capture (HiC). See the review (de Wit and de Laat, 2012) for HiC and related experimental technologies. HiC data are especially useful for associating distal enhancers to their target genes. The utilization of such emerging epigenomic data will make comparative epigenomics more powerful in future studies.

Closing Remarks

In this article, we described conventional methods for comparing epigenomic data with a review of widely-used software and databases. There are many possible ways to compare epigenomic data depending on what kind of epigenomic data and which cell type are used in the comparison. An important point is to combine individual analysis tasks to construct the whole analysis in order to reach a specific research goal. The case study using ADSCs and FatCs provided an example of such analyses conducted in a research setting.

Nomenclature

Common Variant-Common Disease (CDCV) A hypothesis that common variants must be in the genetic background of disease of high prevalence in a population.

Copy Number Variant (CNV) A structural variation within DNA where sections of the genome have been deleted or duplicated in comparison to a reference genome.

Genetic architecture A collective term encompassing the number, frequencies, and effect sizes of causal alleles for a complex phenotype.

Genome Wide Association Study (GWAS) A study that evaluates the genomes of a large population, usually in search of disease-linked genes.

Haplotype An array of alleles that are transmitted together, hence highly-correlated, in a population.

Hardy-Weinberg Equilibrium (HWE) The law that states that allele and genotype frequencies in a population will remain constant from generation to generation in the absence of other evolutionary influences.

Heterozygosity The proportion of heterozygous individuals in each population simply by counting alleles.

Identity by Descent (IBD) The state where two individuals carry the same genetic segment because they have inherited it from a common ancestor.

Linkage Disequilibrium (LD) The non-random association of alleles at different loci in a given population.

Mendelian Following Mendelian inheritance, namely single-gene characteristics that often run in families.

Microarray A sequencing technique involving attaching DNA or RNA fragments to a slide or membrane.

Next Generation Sequencing (NGS) The collective term for modern DNA sequencing technology that can sequence millions of DNA fragments at once in a short amount of time.

Principal Component Analysis (PCA) A technique used to emphasize variation and bring out strong patterns in a dataset by reducing its dimensions.

Quality control (QC) Procedure that examines the data and ascertains its validity, by filtering out substandard data.

Reticulate evolution The concept of the partial merging of lineages that leads to genetic relationships better represented by a network.

Single Nucleotide Polymorphisms (SNP) A type of SNV defined by occurring with high frequency within a population without occurring in the majority of individuals.

Single Nucleotide Variants (SNV) Single Nucleotide Variant. A variant from the reference genome that only differs by a single base.

Whole Genome Sequencing (WGS) A type of NGS which sequences the entirety of the sample genome, both coding and non-coding regions.

Introduction

Population genetics can be defined as the study of patterns of genetic variation to explain genetic divergence within and between different groups of organisms. Its principal methodology includes genetic assessment both across populations and among individuals, and investigating the mechanics of the influence exerted by evolutionary factors on genetic variation.

The early attempts at studying genetic variation were limited to the phenotypes of traits that were clearly heritable, with the most popular trait being the blood groups. ABO, the most prominent blood group classification system, was identified by [Landsteiner \(1900\)](#), leading to a Nobel Prize award in 1930 for this discovery. Incidentally, Landsteiner did not recognize the heritable identity of the trait, which was identified by [Dungern and Hirschfeld \(1910\)](#). [Hirschfeld and Hirschfeld \(1919\)](#) performed the first ever study of human genetic variation using the ABO grouping system as a variable. Later on, molecular techniques enabled the use of genetic markers to identify genetic variation, albeit at a very limited scale. The technological advancements of the last decade have enabled us to efficiently examine large amounts of genetic markers using microarrays or by means of Whole Genome Sequencing (WGS), so that we can affordably and efficiently assess the genome-wide variation patterns to investigate the distribution of variation within and between populations. With these recent staggering technological leaps, we have also witnessed a shift towards the examination of rare variants. Furthermore, the incorporation of ancient genetic data at a large scale has led to the formation of the newly created fields of archaeogenomics and palaeogenomics.

The current scientific era is inundated with genomic data, aimed to be used towards the identification of the genetic background of disease. The alleles that get associated with disease are an important part of the total genetic variation distributed in and across populations, and as such, are influenced by demographic events and natural genetic forces. Population genetics can also supply robust models for hypotheses concerning disease pathogenesis, which can effectively steer medical efforts towards disease prevention and treatment. Studies of linkage disequilibrium patterns in disease gene identification, combined with our knowledge of the human genetic variation, can effectively aid us in our search for disease-causing genes, providing us with deep insight for the investigation of genetic trait mechanics and heritability.

In this article, we provide an overview of the software tools most commonly used in population genetics that are backed by robust algorithms, a description of the steps used when applying them to avoid pitfalls and analytic biases, along with assessment cautions to avoid interpretation biases, but also a brief recital of the fundamental concepts and perspectives of population genetics.

Quantifying Genetic Variation and Perspectives

Population genetics is a discipline that aims to address the issue of inter- and intra-population differences. Hence, it is important to set some boundaries of perspective, by citing some cases that portray the spectrum of genetic differences.

On the one end of the spectrum, identical twins differ, at least at the conception level, at practically none of their DNA base pairs. Any pair of unrelated humans differs at approximately one in a thousand base pairs, being approximately 99.9% identical at the DNA level. From this rate, it can be extrapolated that for any haploid sequence, there are approximately 3 million variants, as indeed evidenced by [Prado-Martinez et al. \(2013\)](#). The latest estimates by the [1000 Genomes Project Consortium \(2015\)](#) have revised that number to the range of 4–5 million, depending on the internal variation of the studied population.

Compared with the chimp, humans are approximately 99% similar for aligned DNA-bases, and by including structural variants, the percentage is reduced to approximately 95% similarity. Interestingly, humans present significantly reduced variation than the other major grade ape species, and can be considered to be relatively lacking in genetic diversity as showcased by [Prado-Martinez et al. \(2013\)](#).

So naturally, our focus shifts next to inquiring about the percentage of the variation shared among major human groups in different geographical continents. [Xing et al. \(2009\)](#) addressed this inquiry by studying four major well-populated regions of the world, namely Africa, Europe, East Asia, and India. They reported that approximately 80% of relatively common variants are seen in all four of these groups, while 88% are seen in at least three groups, and more than 90% are shared in at least two groups. More variation is present in the African samples, with almost seven percent of the common variants seen only in the African subset, while only half percent were seen in any non-African group, which is a commonly observed feature in population genetics.

Genetic variation is most commonly partitioned based on the nature and the allelic frequency of the variants. The [1000 Genomes Project Consortium \(2015\)](#) released the final version of their very dense public WGS panel of world-wide reference populations, cataloguing an impressive amount of genetic variants present in the human genome. The overwhelming majority of the catalogued variants affect one nucleotide, hence called Single Nucleotide Variants (SNVs). Designation of a variant as common or rare is not solidly consistent, with the most common threshold of classification being an allelic frequency of 1%.

Common variants are an invaluable tool for genetic investigative efforts, since they facilitate the detection of constraints in their flow. Rare variation proves to be more challenging to assess properly. The study by [Sudmant et al. \(2015\)](#) exploring the distribution of rare variants, showed that for major continental populations, the great majority of SNVs were found to be population-specific. For frequencies less than two percent, fewer than five percent of alleles are actually shared between any two pairs of continents, which is intuitively sensible because these rare variants arose relatively recently. In the case of rare allele analysis in our genetic studies and our disease-related studies, we need to consider that most rare alleles will tend to be population-specific rather than shared across populations.

Fundamental Concepts Overview

In order to analyze and interpret genomic data, a deep understanding of the structure of the genome is needed, as well as the forces shaping its variation and its function.

In the middle of the previous century, [Wright \(1955\)](#) identified four major factors of evolution, namely mutation, natural selection, genetic drift and gene flow. Mutation is the main force that creates variation in the genome. Natural selection acts by selecting in favor of variants that are beneficial, and selecting against variants that are harmful. Genetic drift introduces the stochastic element in evolution, with populations of limited size presenting significant changes over time in allelic frequencies. And lastly there is gene flow, the transmission of genetic material from one population to another which can be regarded as the homogenizing force. The result of these factors is the complex landscape of individual-level, population-level, and species-level variation.

Landmark studies by [Roach et al. \(2010\)](#) and [Conrad et al. \(2011\)](#) have recently been able to directly estimate the human mutation rate by investigating WGS in a human family, comparing parents and offspring and discovering that the human mutation rate from generation-to-generation is in the order of approximately one in a hundred million base pairs per generation, meaning we transit with each gamete approximately 30–35 new DNA variants. That estimate has recently been confirmed in a number of subsequent studies so we can assert that we have an accurate estimate of the rate at which new variation enters the human genomes. The rest of the factors are heavily influenced by geography and demography, and their elucidation requires population genetics analysis.

Linkage Disequilibrium

Given the trans-generational dynamic state of the genome, it is important to infer loci that tend to accompany each other across generations and shape heredity. That inference can be performed by investigating the correlation between alleles and their associations. An array of alleles in different loci that are non-randomly associated with each other is termed a haplotype.

Linkage Disequilibrium (LD) is a term coined to describe the non-random association between alleles of genetic loci that lie in proximity to each other. Initially described by [Lewontin and Kojima \(1960\)](#) the term was an obscure part of genetics, until its resurface in modern genetics with the analysis of large-scale genomic data. The LD between two loci, A and B, can be quantified by the D_{AB} metric. If we define as $P_{A_1B_1}$ the frequency of haplotype A_1B_1 , P_{A_1} as the frequency of allele A_1 , and P_{B_1} as the frequency of allele B_1 , then D_{AB} is defined as:

$$D_{AB} = P_{A_1B_1} - P_{A_1}P_{B_1} \quad (1)$$

Based on this equation, when D_{AB} equals to 0, then the alleles are in linkage equilibrium, thus are in statistical independence, much similar to Hardy-Weinberg Equilibrium (HWE) premises. For its correct interpretation for non-zero values, the D_{AB} metric should then be normalized to accurately portray LD, since D_{AB} possible values are heavily influenced by the allelic frequencies. [Lewontin and Kojima \(1960\)](#) used the D'_{AB} statistic, which is the ratio of D_{AB} to its maximum possible absolute value. This metric does provide accurate results in the case of similar allelic frequencies, but could be inflated in the case of small sample number or if one of the alleles is rare.

Another very popular normalization method is the transformation of D_{AB} to the correlation coefficient r^2 , by dividing the square of D_{AB} by the allelic frequencies in both loci. This equation is more sensitive for rare alleles, but could prove to be underpowered when detecting haplotypes that may contain rare alleles.

$$r^2 = \frac{D_{AB}^2}{P_{A_1}P_{A_2}P_{B_1}P_{B_2}} \quad (2)$$

Geneticists most often rely on both metrics to get a more complete reading on the linkage disequilibrium between two loci. It is worth stating that these descriptive statistics offer no explanation on the reason for these non-random associations between alleles, and a meaningful interpretation should include at least these two statistics, since each statistic has its own advantages. These equations can also be extended to include multiple loci for investigation, instead of only two. However, their practicality is limited, and regional LD is most commonly calculated with a pairwise model.

Haplotypic Phase

Regional LD analyses through D_{AB} reveal the extent of regions with LD-clustered SNVs, which are commonly referred to as haplotypic blocks. Haplotypic blocks are in essence the estimates of the haplotypic phase of the corresponding real genomes.

The use of haplotypic data is an excellent approach to maximize the information gained from genotyping and sequencing experiments, since the mechanics of heredity are largely powered through the transit of a single chromosome out of every chromosomal pair from each parent. Experimental methods to produced haplotypic phased data are still not adequately efficient and cost-effective, thus the haplotypes have to be estimated through statistical procedures from the genotypic data. The genotypic data produced are unphased, meaning that at heterozygosity there is no direct assumption on the parental derivation of each allele.

Haplotypic phase estimation can be performed by some well-established algorithms. Because of the statistical nature of the estimation, there are limits to the confidence levels for the haplotypic phase of the genotypes. The accurate estimation of haplotypes from high-throughput genomic data is an active field of computational and genetic research that is constantly improving. We will outline the methods used to identify haplotypes in a subsequent section of the article.

Analytic Methods and Strategies

The technological advents of the modern era have produced a wealth of data in the field of genetics. As with other big data fields, a main goal is the statistical exploration of the data and the inference of a meaningful interpretation. In this section we will outline the methods currently employed by population geneticists to investigate population genetics data.

Exploratory data analysis techniques are well established in genetics studies. In the case of population genetics, we mostly focus on graphical techniques, with one of the most important techniques being the ones pertaining to dimensionality reduction. Model-based clustering methods are equally well represented, with a variety of established algorithms used extensively. Of course, for the techniques to be used successfully, the datasets should be well maintained, with appropriate quality control steps that will minimize false-positive results and guide towards a meaningful interpretation of the data.

Quality Control

For quality control purposes, PLINK is an invaluable suite of software tools for the manipulation of genetic data, originally developed by [Purcell et al. \(2007\)](#) and further refined and augmented by [Chang et al. \(2015\)](#). It introduced the most popular format for storing and analyzing genotypic data, the binary PED format, providing high compression along with great computational efficiency.

In genome-wide population genetics, it is usually not feasible to generate all data from a specific institution, so in the majority of cases the bulk of the data derives from a variety of sources that are publically available, or available upon request. Specific care should be applied when merging datasets of different origin, since platform and batch differences could lead to false-positives in the analyses that could compromise our results. This necessitates specific quality control steps to avoid batch effects.

Merging multiple-origin datasets requires a streamlined procedure, since the merging process attends to two datasets at a time. The recommended routine is to first aim to merge together all the datasets that have derived from the same technology, e.g., datasets that have been genotyped on the same microarray chip, or datasets that have been sequenced using the same method. Even when merging datasets generated from the same technology, there are bound to be some markers that are overlapping, but with different annotation details, such as genomic mapping position. In that case, the recommended procedure is their removal, since this error most commonly is a result of a specific marker mapping to multiple regions in the genome. Then a batch effect quality control should be performed on these supersets separately, and then repeat the previous steps, with this step aiming to merge together supersets of each technology.

Avoiding batch effects can be a thorny endeavor, in a field that aims to identify cross-population variation. The study of the genetic background of population *de facto* includes the assumption of genetic flow barriers, so instinctively HWE cannot be utilized in studying batch effects, as the case would be in a common GWAS analytic protocol. In turn, we employ genome-wide missingness patterns to infer batch effects. First, a genome-wide dataset-spanning call rate threshold of 95% should be used for all markers, removing samples that fail to cross that threshold, in order to achieve a basic level of homogenization in our data. Then, an Identity-by-Missingness (IBM) matrix should be constructed, which is very similar to the Identity-by-Descent (IBD) matrix but differs in that the metric used is similarity in missingness patterns. Its visualization by using a heatmap then enables the identification of missingness clusters that could bias results in downstream analyses. In the case of cluster formation, the recommended routine is to perform of the same call rate threshold of 95% to the clustered sample subgroup and the removal of the culprit markers.

In population genetics, geographical and qualitative regularity in sampling is crucial. Even though researchers apply extensive care into avoiding irregularities, it is possible that sampling mishaps do occur. The construction of an IBD matrix enables the investigation of cryptic close genetic relationships between samples, e.g., relatives, that could confound the results, especially in the case of IBD segment detection. Another common phenomenon is the appearance of genetic outliers. These outliers should be examined carefully to validate their outlier status. Population genetic analysis is based on the average of the genetic background in a specific region, and it is possible that some rare variation could create outliers out of otherwise fine samples that just happen to have an inversion that distinguish them from other samples. Specific areas that are prone to structural variation are relatively well known, such as the 17q21 inversion, which population genetics is a separate subject in its own. Inclusion or exclusion of such areas from the analysis depends on the aim of the analysis.

It is also worth considering that the type of analyses that will be performed is highly dependent on the density and the number of markers. For dimensionality reduction methods, as well as modelling-based clustering methods, it has been shown by [Patterson *et al.* \(2006\)](#) that the number of markers to distinguish between different populations is inversely proportional to the genetic distance between the population. A useful metric for genetic distance is the F_{ST} , which will be described in the next sections.

Quality control is a very important aspect of population genetics, but its specifics are versatile, based on the aim of the analysis and the regional characteristics of the samples. Thus, it is strongly recommended that the aims of a population genetics analysis are extensively laid out before formulating a quality control strategy.

Dimensionality Reduction Methods

Traditional methods of phylogenetic analysis relied on data of low dimensionality. Current technology has since enabled the output of high-dimensional data, that are projected to scale upwards as time and technology progress. Dimensionality reduction methods facilitate modern genetic analysis and interpretation by converting large-scale genotypic data to a low number of elements. In this section we will cover the Principal Component Analysis (PCA) method, the most robust and representative method for dimensionality reduction, as well as some of its modifications that suit more specialized analytic protocols.

PCA has been in use in genetics for a long time, since the middle of the century, with [Cavalli-Sforza *et al.* \(1994\)](#) using it extensively in their landmark genetic studies. Notably, its earliest uses were on low dimensional data, condensing phenotypic, as well as genetic information. The technological advances of the past recent years has since shifted to analyzing large scale individual-level data. PCA was shown to be an excellent method to reduce the dimensionality of high throughput genetic data by [Patterson *et al.* \(2006\)](#), who developed the EIGENSOFT software suite to enable the easy application of the method on various popular genomics data formats.

PCA on genomic data can be affected by highly correlated markers and long-range high LD genetic regions. An efficient way to overcome such hurdles is to perform a pruning step to only keep SNPs that are relatively independent from each other in the genome. To avoid highly correlated markers, a simple implementation of a pruning step by specifying a window size of 200 SNPs, a window step of 5 SNPs, and a LD correlation r^2 value of 0.1 is sufficient.

Usually the genomic matrices that are used as input for PCA are nearly complete, with very low missing data. There are instances in population genetics, where specific samples cannot be fully covered, such as in the case of samples that are genotyped on specific markers, or in the case either of ancient and partially degraded nucleic samples. In such cases, these samples can be projected onto the eigenvectors calculated from the complete datasets. The best practice for PCA projection is using a least-squares approach to project the samples with missing data onto the calculated eigenvectors, so that the missing data will not be replaced by the average of the allelic frequencies in the reference data. This approach presents one drawback, referred to as shrinkage. Shrinkage is a notable phenomenon that occurs when solving by using the least-squares approach. An approximate method to efficiently address this problem was also implemented in the latest version of EIGENSOFT, which enables the more accurate projection of data when using the least squares approach.

The popularity of PCA for genetic analysis spawned many algorithms and methods to assess genetic data. Some notable modifications of PCA were designed to run on haplotypic phased data to also infer local ancestry. Haplotype resolving and haplotype-based methods will be described in the following sections, but it is worth mentioning such methods in this section, as the algorithms behind them are based on PCA. This different approach of PCA was utilized by [Brisbin *et al.* \(2012\)](#), in their software package PCAdmix. It is of note that PCA is only a part of this approach, and another step using a forward-backward HMM algorithm to assign ancestry is implemented. They proposed an algorithm that identifies LD-blocks of genetic data, used them as a guide to create genetic bins and perform PCA on every bin to identify patterns of shared inheritance. Using the forward-backward algorithm, PCAdmix is able to calculate the posterior probability for the shared ancestry for each bin by calculating the distance between populations.

PCA is a fast, non-parametric method of identifying population structure and substructure. However, PCA by itself does not assign ancestry to samples and is mostly used for a graphical representation of the data. Ancestry assignment can be achieved by using statistical clustering methods on the output of PCA.

Modelling-Based Methods

Genetic clustering methods can be roughly subdivided into two major groups, the modelling-based and the distance-based methods. Modelling-based methods use population genetic models to classify individuals into potential ancestry groups. Their inherent assumption is that the observations in each cluster are randomly drawn in a parametric model, and they aim to jointly infer the model parameters along with the cluster membership coefficients. Since they are based on population genetic models, they are traditionally more computationally expensive than PCA. Each computational run is based on the premise that each individual is the result of admixture from a number of different hypothetical ancestral populations. Based on this model, they produce an array of coefficients for each individual. Each coefficient is a quantified estimate for a calculated genetic contribution of a hypothetical ancestral population. The number of hypothetical ancestral populations is finite for each run of the algorithm, and will henceforth be referred to as the K value.

These individual membership coefficients for each ancestral population are probabilistic estimates and are translated into admixture proportions. These admixture proportion estimates for each individual are stored in matrices, referred to as Q matrices. These Q matrices can then be used to visualize and identify clusters of individual ancestries. Many approaches have been developed for this type of analysis, mainly differing on the statistical method employed, or their approximations. The choice of software depends on the nature of the constraints of the analysis, be it efficiency, resources, or depth of genome coverage.

[Pritchard *et al.* \(2000\)](#) developed STRUCTURE, the first software reported to use a model-based clustering method to identify population structure. STRUCTURE uses a bayesian approach and a Markov Chain Monte Carlo (MCMC) algorithm to sample the posterior distributions. The last extensions of the original STRUCTURE software were described by [Hubisz *et al.* \(2009\)](#), leading to the current version of STRUCTURE. The models employed by this version also allowed STRUCTURE to account for LD between markers. STRUCTURE was a novel approach to identifying population structure, and was met with great success when investigating strong population structure, though it presented significant flaws when population structure was weak. That success and shortcomings of STRUCTURE created a surge of ideas to increase accuracy and to expedite computational speeds, since the procedures followed by STRUCTURE were computationally intensive, and the number of the markers available for analysis were ever-increasing.

ADMIXTURE was developed by [Alexander *et al.* \(2009\)](#) as an alternative computational method, based on the likelihood approach employed by STRUCTURE. ADMIXTURE uses a maximum-likelihood approach instead of sampling the posterior distribution, employing a block relaxation algorithm to update the Q matrix. By combining a fast block relaxation strategy and a quasi-Newton convergence acceleration, while opting to compute standard error estimates rather than confidence intervals, ADMIXTURE achieves computational speeds up to two magnitudes greater than those of STRUCTURE, while being more accurate, especially in the case of weak structure.

Also responding to the need for better computational speeds and accuracy, [Raj *et al.* \(2014\)](#) described a new approximation method to accelerate and improve STRUCTURE, in a new software package named fastSTRUCTURE. FastSTRUCTURE introduces two new computational solutions that serve different analytic needs, the simple prior and the logistic prior. The simple prior can be used as a first investigative step, as computations with it are significantly faster, on par with those of ADMIXTURE. The logistic prior can then be used on specific K s to identify subtle and weak population structure.

ADMIXTURE succeeded in significantly speeding up the runtime, in the order of $O(K^2Ln)$, where L is the number of loci and n the number of individual samples. A newer method, sNMF gained tract in the recent years, due to reducing the complexity to the order of $O(KLn)$, while being competitively accurate. sNMF is a method developed by [Frichot *et al.* \(2014\)](#) who used a sparse non-negative matrix factorization (NMF) algorithm and a least-squares optimization approach, an idea based on the theoretical connections between PCA, likelihood and NMF approaches. This method is able to compute admixture proportion estimates with similar accuracy to ADMIXTURE and STRUCTURE, while also being ten to thirty times faster. Additionally, sNMF appears to be adept at analyzing inbred lineages of samples, achieving more accurate results than its competitors. The rewards of using sNMF's algorithm in large datasets can be fully reaped when large numbers of K are considered.

Notably, these algorithms infer global scale ancestry, that is, they produce whole-genome estimates of ancestry, and do not identify the ancestry of particular genomic segments. To that end, the Chromopainter/fineSTRUCTURE approach was developed by [Lawson *et al.* \(2012\)](#). This approach involves the painting the chromosomes of each individual, creating a coancestry matrix by

estimating the genetic relationships between all pairs, and using the matrix to infer groups. Practically, it requires the input of haplotypes instead of markers, which can be calculated by specialized software, such as BEAGLE developed by Browning and Browning (2007), SHAPEIT by Delaneau *et al.* (2013), fastPHASE by Scheet and Stephens (2006) or EAGLE by Loh *et al.* (2016). FineSTRUCTURE has two methods of operation, based on utilizing LD information or not. The unlinked method can outperform STRUCTURE in some cases when datasets with a large number of markers are used, but the core of fineSTRUCTURE's strength lies on its linked method, which has the power to identify subtle differences in population groups with finer population structure.

As with PCA-based methods, strong LD could be detrimental for these analyses. It is recommended to remove strongly linked markers, by specifying a genomic window, in the same fashion that was described for the PCA-based methods, albeit with a more permissive r^2 threshold. Care should be taken when setting LD thresholds, since most of those methods do not explicitly account for LD between markers. The authors of the methods often opt to conceptually partition LD based on its demographic implications. Hence, the LD attributable to ancestry differences between individuals is termed as *mixture LD*, the LD differences caused by recent admixture *admixture LD*, and the rest that is influenced by population history *background LD*. LD pruning can limit background LD, but again, if the aim is the intra-population investigation of genetic history, then it could prove to be detrimental for the analysis.

In the case of missing or masked genotypic data, both ADMIXTURE and sNMF fare very well when dealing with missing or masked genotypes, even in the presence of relatively high (<20%) genotypic missingness. Nevertheless, keeping the missingness thresholds to GWAS standards (<2%) is recommended for all of the aforementioned model-based methods.

Identity by Descent-Based Methods

IBD describes identity through common descent, although the IBD segments are not necessarily identical through the rise of mutations during transgenerational transmission. Since the number of mutations and events amassed in each segment is directly proportional to the generational distance to the common ancestor, that information can be leveraged to infer genetic distance. Analyzing IBD sharing patterns can provide insights into past demographic events, migrations and population size fluctuations.

The longer the IBD segments identified between individuals, the more recent the genetic relatedness among them. Shared IBD segments tend to be rare, but when analyzing large datasets, there is a higher probability of detecting them, and those segments can be relatively long. In a dataset with n individuals, the number of possible IBD sharing pairs is $\binom{n}{2}$. The number of samples needed for that type of analysis require fast and computationally efficient algorithms, so that these analyses can become feasible.

The IBD calculation method implemented by Purcell *et al.* (2007) has the advantage of being a fast method, that does not require phasing of the genotypic data. It implements a hidden Markov model for IBD to determine the posterior probabilities. However, it does not account for LD between markers and requires a previous LD pruning of the data, which can lead to a severe loss of information.

GERMLINE was developed by Gusev *et al.* (2009) and used a novel hashing and extension algorithm to detect IBD segments. This haplotypic dictionary approach greatly speeds up IBD detection, with the runtime being analogous to the number of samples, far reducing the amount of computations required by the theoretical model described above.

Browning and Browning (2013) developed a series of algorithms for efficient and accurate IBD detection, with the latest, most improved one being BEAGLE's RefinedIBD algorithm. The algorithms preceding RefinedIBD were computationally intensive and solely relied on hidden Markov models and posterior estimations. RefinedIBD investigates IBD sharing in two steps, one that incorporates GERMLINE's method, and a second refined step that performs the evaluation of the candidate segments produced by the previous step through a probabilistic approach. Due to its nature, RefinedIBD can deliver the highest accuracy of the aforementioned algorithms, while also being computationally efficient on large datasets.

In the case of datasets comprising of unrelated individuals, IBD sharing detection can produce a wealth of information about the demographics of the included populations as well as the evolutionary forces that act on specific areas in different population groups.

Distance-Based Methods

Distance-based methods attempt to measure descent, and they are based on the concepts behind IBD. These methods can be utilized to calculate the distances between all pairs of individuals to produce a population pairwise distance matrix, that can then be further manipulated into a graphical tree-based output. The phylogenetic concepts behind the distance-based methods can be difficult to grasp by an aspiring population geneticist, but they are the fundamentals of population genetics. Here we attempt a brief outline of the methods and their history.

Wright (1921) proposed the first method for distance measurement, the inbreeding coefficient. This measure was later extended to become the F -statistics, a well-established family of statistical methods for measuring population differentiation and the calculation of genetic distances. Introduced in the middle of the previous century independently by Wright (1949) and Malécot (1948), F -statistics are measures of differentiation, statistics used to calculate the amount of variation in the entire population that is attributable to population differences and subdivision. F -statistics can provide valuable insights into population differentiation and due to that they became the most applied methods in population genetics, leading to the spawning of an abundance of related statistics.

Several definitions exist for the F -statistics, and can be partitioned into three main coefficients. The most popular one is the F_{ST} , also referred to commonly as θ . It is defined as the proportion of genetic diversity due to cross-population difference in allelic frequencies, and is dependent on the deviation of the genotypic frequencies from the HWE, assuming linkage equilibrium.

The computational estimation of F_{ST} is complicated, and has been the subject of many published theoretical studies. A simplification of the estimator of F_{ST} was described by [Weir and Cockerham \(1984\)](#). For this simplification to be theoretically valid, a large number of populations are needed, with each population having an large sample size equal to that of the other populations. These assumptions lets us consider that $1/r$ and $1/\bar{n}$ can be ignored from the full formula, leading to this simplified form:

$$F_{ST} = \frac{\sigma_p^2}{\bar{p}(1 - \bar{p})} \quad (3)$$

where σ_p^2 is the variance of the allelic state and $\bar{p}$ is the total average allelic frequency. This simplified form is rarely the one used, with most published estimates of F_{ST} using the full estimation formula. The estimator by [Weir and Cockerham \(1984\)](#) is the most commonly used estimator out of a series of published estimators by different authors, with each possessing different strengths and shortcomings. Markedly, the EIGENSOFT package implementation uses the estimator proposed by [Hudson *et al.* \(1992\)](#), with [Bhatia *et al.* \(2013\)](#) arguing in favor of its robustness to sample size fluctuations and it not leading to overestimations of F_{ST} .

These F_{ST} distances can then be incorporated and fitted to a tree. The inception of the tree-based representation can be traced to the studies of ([Cavalli-Sforza and Edwards, 1967](#)), that used F_{ST} distances to infer phylogenetic trees.

[Patterson *et al.* \(2012\)](#) built on the ideas of the F -statistics to develop a new distinct set of statistics, confusingly named also f -statistics -albeit with a lower-case f for notation- published as part of the ADMIXTOOLS package. This set includes a host of methods for distance measurement, the two population test f_2 , the three-population test f_3 , the four population test f_4 and the qpGraph. They were developed in a quest to infer treeness, admixture and its proportions, founder populations, and complex past demographic events. These methods were extremely successful, inspiring the publication of a series of high-impact papers on the study of modern and ancient population genetics. In brief, f_2 can be considered as a genetic drift measure, f_3 as an admixture test and f_4 as a test of admixture proportions and directionality. Before analyzing for admixture, it is important to test our populations with a treeness test, because in the case of complex admixture events, it is often very difficult to describe past demography with a phylogenetic tree. Even in the case of treeness, the proposed tree should be fit to the data with a certain confidence.

The qpGraph is an admixture graph fitting method that shares similarities with the TreeMix method. TreeMix was developed by [Pickrell and Pritchard \(2012\)](#) and constructs phylogenetic trees by incorporating migratory models. The main difference between those two methods is that while TreeMix explores the possible model space to identify the one that best describes and fits the data, qpGraph uses a proposed model and tests it to investigate its fit on the data. Those migratory models produced by TreeMix, can provide insights into possible admixture events, but provide no info for a proposed date, they are only suggested based on the allowances set by the researcher. Methods that can estimate and date migratory events have been also developed and methodologically constitute a group of their own.

Admixture Dating Methods

Admixed individuals carry the haplotypes of their ancestors, which can be identified by the investigation of LD patterns, namely ancestry tracts. Throughout the generations, the ancestry tracts in the genome can be broken and intercepted by recombination. Thus, in the case of admixed populations or individuals, it is plausible to infer admixture dates by investigating the length distributions of the ancestry tracts.

Dating admixture events between populations was traditionally practiced by studying historical evidence and subsequently reverse engineered to investigate genetic patterns in the data. High density genome-wide genetic data enabled the investigation of LD-blocks, enabling the study of breaks in haplotypes between different populations. This knowledge can be leveraged to measure the transgenerational decay of LD-blocks and infer relative admixture dates.

ROLLOFF is the first reported software to infer admixture dates based on LD decay. The method was first reported by [Moorjani *et al.* \(2011\)](#) and was later incorporated in the ADMIXTOOLS software package developed by [Patterson *et al.* \(2012\)](#) to enable admixture studies across human history. It aggregates pairwise LD measurements using a weighting scheme, to produce a weighted LD curve as a function of genetic distance. This results in an exponential LD decay, and, given a rate constant, it can be further used to infer admixture dates.

[Loh *et al.* \(2013\)](#) built on the ideas of ROLLOFF to develop ALDER, a more sensitive algorithm that incorporates the information of the amplitude of the weighted LD curve to interpret further admixture parameters, enabling inferences on history, such as admixture dates and admixture fractions, or even to infer phylogenetic relationships. The latest extension of the method, MALDER, is able to additionally infer multiple admixture events. ALDER performs very well for two-way admixture hypotheses, but is limited to admixture events less than five hundred generations ago.

The aforementioned methods are used on genotypic data and rely on LD calculations to produce the decay curves. However, they are susceptible to performance issues when dealing with large scale datasets. Newer approaches suggest that utilizing haplotype information can produce more efficient and accurate results. GLOBETROTTER is a method described by [Hellenthal *et al.* \(2014\)](#) that is based on the Chromopainter output to infer admixture dates. Chromopainter is an efficient method that can paint chromosomes based on an ancestry estimation model using large scale data of the tested population and surrogate populations. The resulting haplotypes are then used by GLOBETROTTER to estimate the pairwise likelihood of these haplotypes being painted by these surrogate populations. These haplotypes are analyzed at a range of genetic distances to produce coancestry curves, to an exponential decay curve output similar of the previous methods. The advantage of this method is that the admixing sources are modelled as a linear mixture of surrogate populations, which enables the non-exact sampling of the source populations and the

use of larger geographical groups as surrogates. This method is best used to infer later dates of admixture, and produces a wealth of information, but can underperform when using less than 300,000 markers.

Instead of fitting an exponential LD-decay curve, [Pugach *et al.* \(2011\)](#) developed stepPCO by following a PCA-based approach. StepPCO applies PCA stepwise to identify block-like admixture signals and computes discrete wavelet transform to calculate frequencies and position from the sum of waves in each signal. The dominant frequencies are then compared to the calculated ones to generate the admixture rates. [Sanderson *et al.* \(2015\)](#) provided some extensions to the stepPCO method, accelerating the runtime and improving the statistical power when differentiating between separate admixture events, but limiting it to only two-way admixture hypotheses. StepPCO also requires haplotypes as input, which can be estimated with the appropriate software that were described in the *Modelling-based methods* section.

Each of these admixture dating methods possess various advantages and disadvantages, thus the use of multiple methods is recommended. A limitation that all these algorithms share is their inability to explore genetic events over 5000 years ago, which makes those algorithms better suited for more recent admixture events.

Network Analysis

Network theory, as the study of graphs for related discrete objects, can be applied to genetic data to infer relationships between the samples. The results of the previously mentioned analytic methods can be integrated towards the construction of nodes and edges to create interpretable graphs. Network analysis provides in depth visualizations for multi-dimensional data.

In population genetics, in the case of the aforementioned analytic strategies, we often resort to a specific series of assumptions, a major one of them being that populations emerge in the form of a tree and deriving from a set ancestral population and collectively refer to every other genetic influence as admixture. Network theory can aid the exploration of past demography, by employing the principles of reticulate evolution into our data. As described earlier, in many cases, there are no specific trees that can explain the data, with multiple lineages merging or converging to form new populations. In such cases, reticulate patterns of demography can occur. The integration of network theory into population genetics and phylogenetics can act as a valuable tool to address such issues.

Phylogenetic networks can be divided into two main categories, the unrooted and the rooted networks. Numerous methods have been developed for both types of networks, some of which have achieved popularity. Software packages have been constructed in an effort to encompass the most mainstream of them for the ease of the user. In this section we will briefly describe some of these approaches and the theory behind them.

SplitsTree is an interactive application developed by [Huson and Bryant \(2006\)](#), that infers unrooted networks from genetic data. It also includes the NeighborNet algorithm, which was introduced by [Bryant \(2003\)](#) to construct split networks from measured genetic distances. Dendroscope was also developed by [Huson and Scornavacca \(2012\)](#), with the goal of inferring rooted phylogenetic networks, integrating algorithms such as the CASS by [Iersel *et al.* \(2010\)](#), the cluster network by [Huson and Rupp \(2008\)](#), and the galled network by [Huson *et al.* \(2009\)](#). These programs can accept pairwise genetic distance matrices or sequence alignments to infer reticulated demography. A commonly chosen metric for these calculations is F_{ST} , as described in a previous section.

NetStruct is a newer package developed by [Greenbaum *et al.* \(2016\)](#) that draws from the community and modularity methods included in the *igraph* software package, described by [Csárdi and Nepusz \(2006\)](#), to create networks and infer population structure. For input it requires genotypes, in contrast to the previous methods, but it does not account for linkage disequilibrium, which is one of its shortcomings.

[Paschou *et al.* \(2014\)](#) and [Stamatoyannopoulos *et al.* \(2017\)](#) developed a different approach into network inference. Instead of using F_{ST} or traditional phylogenetic methods, they opted to infer networks from the output of PCA and ADMIXTURE. To form the networks, they identified the top few nearest neighbors of each sample by representing each sample with respect to the top K coefficients returned by PCA or ADMIXTURE, and then computing the distance of each sample to all other samples that do not belong in the same population. In the resulting network, an edge between two populations shows that the two populations share genetically related individuals, with thicker edges indicating a larger number of genetically close individuals, which gives insights into the pathways of inter-population genetic flow.

A newer method was introduced by [Zhang *et al.* \(2017\)](#), who deployed the ideas behind chromosome painting and NeighborNet to combine them using a Markov clustering approach. This approach features the investigation of recombination events, an increased resolution of shared ancestry, and the determination of the number of clades.

Networks are an important part of population genetics and phylogenetics, since reticulate evolution is the rule, which most times in phylogenetics we tend to disregard because of the model assumptions and its complications. Networks deviate from the rigid tree-like structure, and lead to a broader concept of population emergence and admixture. Of course, no method escapes all biases, so careful examination, along with a global exploration of the data is recommended.

Scanning for Selection

The methods explored in the previous section have a limit to their detection timescale. When investigating events in the far past, the effect of the evolutionary selective forces becomes increasingly evident. In this section we describe microevolutionary theory in conjunction with its applications on population genetics.

Natural selection creates regions of strong LD, raising the possibility of reverse engineering information about natural selection in populations. Considering that a new variant arises on a chromosomal background, there will be SNPs nearby in strong LD that are highly probable to be shuffled by recombination into increasingly smaller haplotypes through generations, which are going to be associated with that variant. Under a neutral model, this variant is expected to increase in frequency gradually so that by the time it attains higher frequencies, it will be on a relatively small associated SNP haplotype background.

If there has been rapid positive selection for that variant, it will essentially drag the nearby SNPs along with it and we will be able to identify a region of high linkage disequilibrium because this variant has evolved quickly to high frequency, so quickly that recombination was late to reshuffle these nearby SNPs. This is one of the signatures that indicates a region that underwent recent and rapid selection. To avoid false positives, it is suggested to remove low complexity regions, as well as the highly-complex HLA region, due to our limited knowledge into their genetic mechanics.

The detection signatures of selection is a vast category of analytic methods that is further divided into three subcategories, the frequency-based methods, the linkage disequilibrium-based methods, and the population differentiation-based methods. It is of note that, when selecting the analytic method, the timescale over which we hypothesize that selection has acted upon is considered to have a major effect in our analysis. Each method by its inception has fundamental advantages and disadvantages. Methods that rely on population differentiation and allelic frequencies have an advantage in large timescales, due to their inherent assumptions.

By Allelic Frequency

Since a selected genomic region can affect the allelic distributions in populations, statistical tests investigating allelic frequency patterns were developed to detect deviations from the neutral theory of evolution. Tajima (1989) was the first to introduce such a selection metric, referred to as Tajima's D . It operates by comparing the average pairwise difference between samples to the number of segregating polymorphisms. It is the most popular metric to detect selection signals, and spawned an array of derivatives.

The H metric by Fay and Wu (2000), building on Tajima's D , compares the pairwise differences to the samples that are homozygous for the derived allele. H measures the deviation from neutrality as they manifest between high and intermediate allelic frequencies, while D between low and intermediate allelic frequencies. Continuing this line of thought, Zeng *et al.* (2006) introduced E , which measures between high and low allelic frequencies, while putting less weight on high allelic frequencies. The combination of all of these metrics can act as an indicator of population expansion and distinguish it from purifying selection.

Fu and Li (1993) developed two metrics, F^* and D^* for the examination of singleton mutations. The D^* metric compares the average pairwise differences to the singleton mutations, and the F^* compares the average nucleotide differences to the singleton mutations. Of these two statistics, F^* is considered to be the one with the greatest power. The R^2 , introduced by Ramos-Onsins and Rozas (2002), also utilizes singleton information and improves upon the previous method by comparing the differences between the average nucleotide differences to the singletons in each sequence, and also accounting for ascertainment bias in the use of genotype microarrays.

The timescale on which these methods operate is indeed vast. Tajima's D can detect evidence of selection in the past 10,000 generations of human populations, while Fay and Wu's H can detect events up to 3000 generations in the past.

By Linkage Disequilibrium

Selective pressure can create extended regions of strong LD, with haplotypic segments that are consistently inherited through generations. By utilizing the information gained by extended haplotypes, it is possible to infer positive selective pressure.

Sabeti *et al.* (2002) proposed a statistic for the measurement of the decay of LD, called extended haplotype homozygosity (EHH), defined as the probability that two random haplotypes in the sample set are identical by descent. This statistic inspired the development of several influential methods. In the same study, Sabeti *et al.* (2002) developed the long-range haplotype (LHR) test to investigate EHH. Based on the assumption that recent events should have a clearer signal when they extend over 10 times that of the background LD segments (0.02cM), it can detect recent positive selection, typically up to 400 generations in the past. Expanding on EHH, Sabeti *et al.* (2007) also developed the cross-population extended haplotype homozygosity (XP-EHH) test, which examines variation in recombination rates by comparing haplotype lengths among populations to probe for variation in recombination rates. Voight *et al.* (2006) introduced the integrated haplotype score (iHS), a variation of EHH, which attained popularity. It calculates the integral of the EHH decay curve for the ancestral and the derived variants, to provide a measure of the unexpectedness of the haplotypes around a marker relative to the whole genome. These methods are designed to identify alleles that have attained high frequencies in such a rapid fashion that the LD around them has not decayed. While XP-EHH is more suitable with selective sweeps nearing fixation in one, but not all populations, iHS has the power to detect partial sweeps.

Leveraging the information gained by haplotypes, Fu (1997) based the calculation of his F_S on the infinite-sites mutation model to estimate the probability that a random individual would possess an equal or smaller number of alleles compared to the observed values. Fu's F_S is more powerful in detecting population expansions than Tajima's D , and also performs very well in large sample sizes. It is sensitive in the presence of recombination, which could also be used as a test for evidence of recombination. D_h is another measure that uses haplotypic information, introduced by Nei (1987). It is an unbiased haplotype diversity estimate, which computes the probability that two random haplotypes in the sample are different. In a more brute fashion, identified IBD segments, which can be obtained through the methodology described in the previous section, can also

be utilized for the detection of selective sweeps. If a particular IBD segment is enriched in a specific population, then it could be evidence for selection.

These statistics can be significantly affected by erroneous recombination estimates, and as such, when recombination rates are unknown, it is preferred to rely on the statistics based on allelic frequency, preferably Tajima's D or the R^2 . Additionally, as these methods are essentially based on LD, their investigative timescales are much lower than those based on allelic frequency.

By Population Differentiation

Selection patterns can be investigated through the direct measurement of the frequencies of the derived allele between populations. Given a common ancestor, we define the allele that was passed onto its descendants as ancestral, while the allele that was created by mutation as derived. The derived allele is subject to selection, either positive or negative. This difference between the frequencies observed between populations, the δDAF , can be utilized to leverage derived allele frequency differences to infer whether selection has occurred.

F_{ST} , described earlier, can also indicate if diversifying selection has occurred by cross-examining between populations. A genome-wide scan of single marker estimates of F_{ST} can identify regions where natural selection has favored specific alleles in specific populations, with a detection range of up to 3000 generations into the past. In order to properly identify selection signatures using this method, a proper genome-wide background should be specified, depending on the properties of the study. When identifying adaptation to a specific environment, a very similar population that resides in a different habitat should be selected as the background for comparison. F_{ST} can be highly variable when applied only to single loci to study selection, and counter-measure approaches propose utilizing sliding windows to report average or highest values, which can lead to the discarding of valuable information. As with the phylogenetic usage of F_{ST} , scrutiny of the appropriate estimators, as well as the markers to be used is recommended.

By Composite Scoring

Each of the previous categories and tests is designed to detect a particular type of signal. However, the selective process is not limited to a specific signal type, generating a multitude of signal types. The study of a single type of signal can limit the power and the resolution of our inquiries. To that end, there have been efforts to combine multiple metrics based off different approaches into one composite method to attain greater power and resolution.

The composite likelihood ratio test (CLR) is a statistical method introduced by [Kim and Stephan \(2002\)](#) to probe the reduction of variation in local regions, which divides the maximum composite likelihood under a model without selection by the maximum composite likelihood under selection. This approach was successful in utilizing the spatial variation patterns in the frequency spectrum, with the downside of being inefficient for large scale datasets and sensitive to recombination and mutation rate biases. Building on these ideas, [Nielsen et al. \(2005\)](#) modified the CLR method by opting to calculate the null hypothesis from the background of the input data. However, this method does not account for multiple populations, and as such [Nielsen et al. \(2009\)](#), with G2D, and [Chen et al. \(2010\)](#), with XP-CLR, provided extensions to account for cross-population comparisons. The XP-CLR is based on a model-based extension of F_{ST} to compare multilocus allelic frequencies between populations, and is able to capture the spatial patterns of frequency skews that emerge around given markers. XP-CLR is able to better avoid ascertainment bias and demographic uncertainties, while G2D is better suited for when detailed demographic models are available. Additionally, a computationally efficient implementation by [Pavlidis et al. \(2013\)](#), enables the application of the CLR method on very high density data, such as the ones produced by WGS.

Another strategy into composite scoring is the combination of many tests for a single site. [Pybus et al. \(2014\)](#) opted to use combine the results of a variety of methods, combining them using a ranking algorithm to evaluate their significance of the findings. Their method utilizes supervised algorithms in a hierarchical classification scheme, by maximizing the difference between different evolutionary scenarios.

The methods described in this section can be found in standalone executables by their authors, integrated in a variety of community packages of programming languages (e.g., R, python), or in software packages, for example selscan by [Szpiech and Hernandez \(2014\)](#), Sweep by [Sabeti et al. \(2007\)](#), Arlequin by [Excoffier and Lischer \(2010\)](#), and DnaSP by [Rozas et al. \(2017\)](#).

Assessment and Considerations

Assessment of PCA and PCA-derived methods mostly relies on the visualization of the components that capture the most variance. Notably, approximately ninety per cent of the total genotypic variance pertains to intra-population variance, which means that only a fraction of the top principal components will be useful for the correct interpretation of inter-population differences. In most cases, the top three principal components are indicative of population structure, which can be visualized either in a three-dimensional scatter plot, or a combination of two-dimensional scatter plots.

The assessment of model-based clustering methods is based on the use bar plots to visualize the ancestry coefficients that are contained in the Q matrices, which was also one of the major factor that contributed to their immense popularity. This in turn translates to multiple analysis runs for different K s of hypothetical ancestral populations. ADMIXTURE's cross-validation

procedure produces an error estimate that aids ancestry modelling. The lowest cross-validation error value is proposed to be the most sensible K value to be used for ancestry modelling. STRUCTURE and its derivatives rely on the calculation of the marginal likelihood for each K , where the greater the value, the better the fit of the data to the model.

Because of the model that they operate on and their inherent assumptions, model-based clustering methods are prone to misinterpretation. To address this issue, several points must be stressed. Since the K value is an estimate, there is no evidence that it is the true one. The true value of K is highly dependent on sampling and its geographical regularity. In the case that important population groups have been under-, over-, or even unsampled, K estimates will not lead to meaningful interpretation. Apart from its numerical value, the qualities of the K ancestral populations should also be considered. The K ancestral populations could, but could equally not have existed at all in history. These ancestral populations should not be considered homogeneous and unadmixed, and they may as well have been related to each other. The primary assumption of those methods is a unidirectional admixture model, which works in the case of simple population histories but can prove problematic in complex population histories. In such cases, they select the most prominent drift components as they are detected and regard them as ancestral, which can lead to populations close to ancestral frequencies to be regarded as admixed. These methods cannot discern between admixture, retrograde admixture, or population bottlenecks, which can heavily influence the resulting output.

The practicality of distance-based methods is sufficiently multifaceted. They can produce the branches of a phylogenetic tree, they can showcase the shared genetic drift between groups, and they can deduce complex demographic scenarios based on the coalescence times and the internal genealogical branch lengths. The complex nature of this range of interpretations though also raises some points of consideration. The choice of markers is critical for the type of analysis aimed for, with a notable example being the inclusion of genomic areas undergoing strong selection which can confound investigations into past demography. The presence of LD can also influence the analysis, with current software packages offering elegant solutions to this issue, such as the bootstrapping and the block-jackknife that can produce error measurements. Because the main method of interpretation is through eye examination, the distance measure and the choice of graphical representation may significantly affect the identified clusters. Because of their complex statistical nature, distance-based methods can occasionally be counter-intuitive, and as such, require a deep understanding of the concepts behind them.

In the case of the admixture dating methods, it needs to be stressed that they operate with specific hypotheses. One is that admixture happens in pulses, as single admixture events, and not at prolonged periods of rates. The second is that they take into account only unilateral admixture between pairs of populations. Third, since they require the use of surrogate populations to test their hypotheses, they can open the gates to a flood of biases, especially when selecting the surrogate populations, since most populations are already admixed. In that case, the modern populations should be carefully selected as surrogates and potential biases clearly stated. Their investigative past timeline is also limited, with 5000 years being the lowest bound in the range of inferred dates.

When probing selection sweeps, it is probable that while the neutrality tests can lead to the rejection of the null, the results could prove to be falsely positive. Demographic events may well interject in the performance of the algorithms, and to combat such possibilities, many methods that take into account demographic models have been implemented. Strong LD between a neutral and a selected variant can also create false-positives in the interpretation of the results. Confounding patterns of LD can also arise due to systematic biases. Using genotype microarray data often cause the oversight of markers with lower frequency, leading to ascertainment biases in the analysis.

In all cases, effective and regular sampling is very strongly recommended. All the cited methods are particularly sensitive on the samples used, the genetic differentiation between the populations, and, equally important, on the number of markers examined. Also of note is that the analytic choice of populations should be coupled with an appropriate density in markers. Genetic discrimination between subgroups of an ethnic group, requires a much higher density in markers than discriminating between different ethnic groups. As always, the global use of a variety of different methods is advised. As in the case of model-based clustering algorithms, different software use different estimation or approximation procedures to achieve computational efficiency. Different methods can capture mishaps and erroneous estimates produced by other methods, or can be particularly sensitive in specific genetic signals.

The Peopling of Europe as an Illustrative Case

The genetics of the European continent have provided prime illustrations of the capabilities that population genetics has when applied to study historical demographics. Archeogenetics and population genetics have been able, supported by palaeological and archaeological evidence, to give insight to the population movements that occurred from the transition of the Middle Paleolithic into the Upper Paleolithic and into the modern structure of anatomically modern humans.

Since the landmark studies by Cavalli-Sforza *et al.* (1994), it was evident that genetic components seem to follow continuous clines in Europe, a notion further reinforced by the whole-genome genotype analysis of Novembre *et al.* (2008). Cavalli-Sforza *et al.* (1994) proposed that these clines were the indications for the mass population movements of the Neolithic expansion into Europe, over the Mesolithic and Epipaleolithic populations. Present day knowledge now confirms these notions, albeit in a much more complicated manner than the one originally proposed.

The genetic ancestries of the modern Europeans can be traced to three major genetic influences as showcased by Lazaridis *et al.* (2014): the Mesolithic hunter-gatherers, the anatolian Neolithics, and the migrants from the steppe. To elaborate on these ancestries, a recapitulation of the current state of knowledge is in order.

There has been evidence of a wide distribution of anatomically modern humans by 43,000 BCE in Europe, as suggested by Benazzi *et al.* (2011). This Aurignacian culture is thought to have led to the disappearance of the Neanderthals in a multitude of ways.

The oldest genomic evidence available originates from this exact era, an individual from the geographic area of modern Romania named Oase 1. This individual was reported by [Fu et al. \(2015\)](#) to have 6%–9% Neanderthal ancestry, with genomic tracts extending over 50cM, indicating a Neanderthal ancestor 4–6 generations past. However, the genome of this individual suggests that this population did not contribute in an identifiable way to the genetics of the later humans. The Aurignacian culture was most likely succeeded by the Gravettian culture during the Upper Paleolithic era at approximately 35–30,000 BCE, which was most probably the last unified culture of Europe. [Fu et al. \(2016\)](#), analyzing 51 Eurasians that ranged from the Upper Paleolithic to the Mesolithic era (45,000–7000 BCE), reported that even though there was no detectable genetic influence by these early humans over the modern humans, these people were the likely descendants of a single founder population, with a 35,000 year-old human specimen representing the earliest discovered branch of this population. [Fu et al. \(2016\)](#) also identified a major shift in the peopling of Europe after the last Ice Age and during the major warming period, with the disappearance of the Gravettian culture, and migrants with a significant genetic component attributed to modern Near Eastern populations. This era was most likely the subject of intense population shifts, as it is proposed that these recolonizers were replaced by the eventual future Mesolithic cultures. These Mesolithic cultures are proposed to be a medley of at least two ancestral sources after the last Ice Age period, though with no clear evidence of their origin. Analysis of genomic data from Mesolithic and later populations, such as the studies by [Lipson et al. \(2017\)](#), [Lazaridis et al. \(2014\)](#), [Skoglund et al. \(2012\)](#), [Sánchez-Quinto et al. \(2012\)](#) suggest a genomic diversity background that deviates from the one observed in modern humans, but similarly showing clinal patterns, following an east to west genetic cline.

The rise of the Neolithic Age in the fertile crescent, brought about a major population migration into Europe, initiating during the 8th millennium BCE, leading to the first agrarian societies in Europe by the 7th millennium BCE. These Neolithic migrants conveyed the agricultural technology and culture to the whole mainland of the European continent. Many studies, such as the ones by [Gamba et al. \(2014\)](#), [Haak et al. \(2015\)](#), [Hofmanová et al. \(2016\)](#), demonstrated the genetic entanglement of the Mesolithic and Neolithic ancestries into admixed populations with a 10%–25% Neolithic ancestral component. The exact route followed by the Neolithics was a matter of historical debate, with genetics supplying insights into the migrational routes, as [Paschou et al. \(2014\)](#) demonstrated genetic signatures of a maritime route of colonization that was followed by the Neolithics from the fertile crescent into Europe. This finding has also been supported by [Hughey et al. \(2013\)](#), who inferred from mitochondrial data that the Minoan population was indeed a population closely resembling the Neolithic and modern European populations.

The last genetic component of the modern Europeans derives from a genetic influence from the Eurasian steppe, around the 5th millennium BCE. The studies by [Allentoft et al. \(2015\)](#) and [Haak et al. \(2015\)](#), identified an ancestral component associated with the Yamnaya and the Afanasievo cultures, mostly appearing in the Northeastern and Central Europe. These steppe populations also show distinct signatures of admixture, themselves being an amalgamation of Mesolithic cultures from East Europe and the Caucasus, the Neolithic and later age Iranian fields, as well as modern population components. These suggest that the genetic flow followed a bidirectional route, instead of a unidirectional one.

The nature of the genetic influence over other populations does not always follow the same mechanics, with some genetic signatures involving abrupt genetic influences, and others gradual genetic assimilation. Especially in the case of the steppe genetic influx, the transitions appear to have occurred between relatively short timescales. [Goldberg et al. \(2017\)](#) and [Saag et al. \(2017\)](#) demonstrated that while the Neolithic migrations involved large numbers of males and females, the migrations from the steppe, as well as their genetic influence, were mostly of male origin.

Modern day European population structure is the result mainly of these major genetic influences, with the magnitude of these influences varying by region. The patterns of these genetic components shift based on the genetic flow from these major or from minor sources. [Haak et al. \(2015\)](#) reported a more prevalent Anatolian Neolithic ancestry in southern Europeans than in northern Europeans, and higher percentages of steppe ancestry in north-central Europeans than southern Europeans. The genetic clines initially observed by Cavalli-Sforza, led to the reveal of an intriguingly intricate genetic past of Europe, branching off to the study of the human history over all continents, enabling the exploration of the rise of the modern anatomical humans and their expansion all over the world. Population genetics contributed immensely to that end, supplying an overwhelming amount of data and analytic methods for the investigation and inference of past human demographics.

The study of population genetics has also been exercised on later generations of genetic history, into the medieval and more recent time periods, to investigate and elucidate historical controversies. [Stamatoyannopoulos et al. \(2017\)](#) tested the hypothesis set by Jakob Philipp Fallmerayer, a strong proponent of the theory of the eradication of medieval Peloponnesean Greek populations by Slavic and Avar invaders and the genetic discontinuity between medieval and modern Greeks. The results refuted those claims, indicating a strong genetic similarity of the modern Greeks with modern Sicilians and Italians and a clear differentiation from the genetics of the Slavic homeland. Population genetics also has the remarkable ability to produce historical controversies, such as the case of the remains of King Richard III of England, which were genetically investigated by [King et al. \(2014\)](#).

The study substantiated that, while the maternal royal line was continuous, the paternal one was surprisingly discontinuous, which laid doubts on the right of patrilineal succession of medieval English kings even into the modern royal family.

Application of Population Genetics in Disease

The exact mechanisms that link genetic variation to disease have been a major subject of debate, stemming from the era of classical genetics and reaching to modern genetics. [Fisher \(1919\)](#) laid the foundations for considering polygenic disorders and continuous phenotypes as a combination of multiple Mendelian loci. Expanding on these notions, Common Disease-Common Variant is a

well established hypothesis, tracing its origins on multiple articles but mainly to the landmark paper by Reich and Lander (2001). In essence, it states that for a disease of high prevalence in a population, the genetic components that lead to it should be relatively common in that population.

Following the Common Disease-Common Variant hypothesis and its extensions, when investigating a multifactorial disease, a significant amount of its genetic background should rely on common variance. Since common variance is heavily influenced by demography and evolutionary forces, the implementation of population genetics becomes critical for the avoidance of a result riddled with false positives that can be attributed to population structure in the data.

When the analysis spans an extensive amount of the genome, such as in the case of a GWAS, the use of PCA or model-based clustering methods can sufficiently correct for inflation related to population stratification. Price *et al.* (2006) demonstrated that incorporating the output of the principal components for each individual as coefficients in an association model can alleviate the inflation effects. Alexander *et al.* (2009) also designed ADMIXTURE as a method competing with EIGENSOFT in the calculation of ancestry coefficient for association modelling. Nowadays, it is commonplace to use the output of PCA, or ADMIXTURE or related methods, as coefficients in a logistic regression association model to correct for inflation in the statistics.

However, a critical number of association studies are not performed in a genome-wide frame, especially in the case of replication studies that seek to validate results from GWAS in various populations. In that case, the use of PCA to identify SNPs that carry the inter- and intra-population variance, and their subsequent genotyping along with the investigated markers, is fundamental for the avoidance of bias and confounding related to population structure.

To that end, Paschou *et al.* (2007) developed a PCA-based methodology to infer ancestry informative markers (AIMs), that was able to identify the prime markers capturing the intercontinental and cross-population variance, efficiently reducing the number of markers required for structure identification to a mere handful, though these markers were in general not overlapping among regions. Paschou *et al.* (2008) applied the method in European-American datasets, effectively demonstrating that by using this method, 150–200 AIMs were sufficient to capture the fine details of stratification in individuals that derived their ancestry from Europe. Drineas *et al.* (2010) applied the method to successfully infer geographic coordinates of European population data by using a small subset of the markers, further showcasing the effectiveness of the method and the bridging between population and disease genetics. Through an extension of the method, Paschou *et al.* (2010) demonstrated its applicability in a portable worldwide setting, resulting in a significant reduction of required markers to capture broad and fine-scale stratification to less than 0.1% of the original dataset. These methods were very successful in denoting the power of PCA to decrease study expenditure and increase computational efficiency when controlling for stratification effects in association analyses.

Discussion

Population genetics has a deep impact on the whole field of genetics, shaping many of its fundamentals, and branching off into different subfields. Nowadays we can discern between population genetics, palaeogenetics, evolutionary genetics and spatial genetics. Palaeogenetics, or archeogenetics, as the genetic study of samples that predate the current era, since modern technology has enabled the isolation of DNA of appreciable quality from bone samples and the sequencing of their bases, and spatial genetics as the joint analysis of genetics and geographical space and the investigation of their interaction and co-dependence. We refrained from referring to spatial genetics methods, as we believe that they constitute a subfield of their own, and they would be outside the scope of population genetic analysis. We also skimmed the surface of palaeogenetics and evolutionary genetics, by mentioning some of the methods used for these analyses, that are overlapping with population genetics, but not delving into the complex theory required for their interpretation.

Originally, when drafting an article about population genetics analyses, a dilemma arises faced on the decision on how to classify and showcase the algorithms and the protocols, whether the criterion should be the depth level required of the genetic data, the form of the genetic data, or the algorithmic method on which the software is based on. In this guide, we opted for the latter. We focused mainly on the nature of the base method, than how many variants should be included in the dataset.

High-density data enable what is termed as local ancestry inference, namely the ability to infer the ancestry of specific genetic tracts all over the genome. Global ancestry inference is still very popular, and for a good reason, since the majority of variants are associated through LD, which means that global ancestry inference methods can work on thinner datasets, which is most commonly the case when conglomerating datasets.

Oftentimes, in interdisciplinary research, it is not uncommon that specific terms get misused or mixed. A notable example is referring to a method as “supervised”. Pritchard *et al.* (2000) refer to the term to describe a method that incorporates information to the data that relates to their prior groupings. Other researchers refer to the term as the need to specify their own number of K ancestral populations. There is no correct or erroneous use of the term, as in both cases its use is justified, and we are just using this cautionary example to prevent misgivings when interpreting published analytic protocols.

We can apply the information gained from our studies of genetic variation that pertains to the use of LD in disease-gene mapping. LD essentially reflects the patterns of recombination occurring over many hundreds of generations, especially for closely linked loci, and we can use it to infer the distance between closely linked loci. Populations that were founded a long time ago had more evolutionary time for recombination to occur, which leads to less LD. Specific groups of populations have had a more rapid decay of LD between SNP pairs (1000 Genomes Project Consortium, 2015), which necessitates a population genetics view when pursuing and interpreting disease-associated genomic loci. Since many markers in the genome are in LD with each other, they can

be considered redundant for our analyses, and we can get relatively complete coverage of a genome in a GWAS with approximately 1.5 million SNPs for African derived populations, and approximately a half million to a million SNPs for non-African populations. Thus, studies of population history can inform our design of these GWAS and our design of SNP microarrays.

It is important to note, that the most significant and impactful current scientific advances in human population genetics have been achieved through the study of SNVs. Such variants comprise the overwhelming majority of genetic variation, enabling the capture of a significant amount of variation for study. Another category of variation is the structural variation, with a substantial amount of variation existing at the structural level. These structural variants are more difficult to identify than SNVs, but, as [Sudmant *et al.* \(2015\)](#) reported in their study, we can estimate that in the average haploid human sequence, at least 9mb are affected by structural variants. When compared with the approximately 3.5mb in the average genome that are affected by SNVs, these structural variants, even though occurring less frequently in the genome, account for more differences than SNVs. And if we also consider Copy Number Variations (CNVs), where genetic segments can differ by multiple copies, each human is heterozygous for approximately 150 of those CNVs.

As rare variants tend to be population specific, we can investigate a lot about the functional significance of these genetic variants, because functional regions in the genome, whether coding or non-coding, tend to show more evidence of purifying selection. And we can actually use this information to more effectively identify functional regions of the genome.

The examples of CNVs and rare variation showcase the amount of genetic information that still eludes us. However, the modern technological advances have overcome that limitation, producing more global maps of genetic variation. With the avalanche of genetic data being generated daily, we can await for a wealth of knowledge to be generated in the following years, along with the development of methods that will be able to handle that level of data.

Overview

The practice of modern pharmacological treatment is very much a balancing act between the therapeutic benefit and toxicity or adverse effects of the prescribed drugs. While pharmacokinetic/-dynamic properties of drugs are usually balanced carefully with many exogenous and endogenous factors such as gender, age, weight, comorbid diseases, drug–drug interaction, etc., rarely are impacts of human genetic variation being taken into consideration when it comes to conventional prescription of medications. This is despite the fact that individuals' variation in genes involving in drug reactions/responses (pharmacogenes) within a population and/or among different ethnic groups have well been established to exert a direct impact on the metabolism and hence, the pharmacological efficacy and probable toxicity of drugs (Chung *et al.*, 2004; Hung *et al.*, 2006; Kaniwa *et al.*, 2013). In addition, manifestation of adverse drug reactions (ADRs) and drug efficacy can also vary geographically (Mizzi *et al.*, 2016).

To date, approximately 19,000 genetic variants from about 1600 human genes have been annotated in various databases to play either a direct or an indirect role in drug responses (Pharmgkb, 2017; Whirl-Carrillo *et al.*, 2012). As of December 2017, 255 of these variants are included in the labels of about 200 marketable drugs approved by the U.S. Food and Drug Administration (FDA) (Fda, 2017). This represents a mere 12% of the total number (1607) of FDA-approved drugs. In fact, population-wide genetic variation means that most of the medications are beneficial to only a subset of the treated patients; with the rest remaining either untreated or subsequently developing mild-to-serious ADRs (Schork, 2015; Spear *et al.*, 2001). The National Health Service in the UK has recently reported only 30%–60% “pharmaceutical effectiveness” for drug treatments (Hill, 2015).

“Imprecision” medicine is not only a leading cause of mortality and morbidity globally, the economic burden is enormous too. In the US alone, ADRs were estimated to cost up to approximately 30 billion US dollars annually (Sultana *et al.*, 2013). Until recently, the high costs and technological complexity associated with the precise identification, analysis, and interpretation of genetic variants have hindered the inclusion of these data in the wider pharmacological practices. However, with the advent of genomics technologies, especially that of sequencing and bioinformatics, a vast amount of data on population genetic polymorphism can now be generated. Together with the increasing availability of clinical phenotypes and pharmacosurveillance data, association between these variants and their impacts on drug efficacy and/or toxicity can now be resolved with a much higher resolution at a much lower cost.

This article aims to give a general overview on the population-wide approach to the fields of pharmacogenetics and pharmacogenomics. A particular focus is paid to the different bioinformatics methodologies used in the analysis of population genetic data.

Genetic Basis of Variability in Drug Response

Pharmacogenetics & Pharmacogenomics

The terms *pharmacogenetics* and *pharmacogenomics* are sometimes used interchangeably. The former describes the influence of genetic variants of a single gene or a number of genes on drug response. However, it is evident that many of these genes do interact, either directly or indirectly, and work within a network of drug pathways to contribute to the interindividual differences observed in drug response. Consequently, a comprehensive genome-wide approach, i.e., pharmacogenomics, involving not only the pharmacogenes but also their up- and downstream pathway genes is necessary.

In the simplest sense, for any drug to exert its therapeutic effect after entering the systemic circulation of the body, it has to bind to a certain receptor molecule before being delivered across the cellular membrane to reach and act upon its intended target; and finally with the unwanted end metabolites removed from the body. The cellular transport processes are carried out by the so-called pharmacokinetics (PK) genes, which can affect how a drug is being absorbed into the body and cells, distributed throughout its target sites, metabolized to either active or inactive forms, and excreted out of the body (Fig. 1). On the other hand, the effects of a drug on its targets and associated downstream pathways are mediated by pharmacodynamics (PD) genes (Fig. 1). Some of these PK and PD genes include ATP-binding cassette (ABC) and solute carrier (SLC) transporters, membrane targeting PDZ proteins, drug receptor families such as the G protein-coupled receptors (GPCRs) and various ion channels, and Phase I and II metabolizing enzymes. Among them, allelic variation in the different member genes of the Phase I enzyme cytochrome P450 (CYP450) family have alone been reported to affect the metabolism of up to approximately 25% of all drugs (Ingelman-Sundberg *et al.*, 2007).

Therefore the desirable therapeutic response to a drug is only elicited when both PK and PD genes are functioning as intended. However, variation in any of these genes may also result in “off target” effects that can cause adverse reactions (Karczewski *et al.*,

Fig. 1 A workflow of pharmacogenetics/-genomics. The workflow depicts the common steps typically taken to identify a pharmacogenetic allele responsible for a drug response in a population. Variants discovered through various genotyping platforms in patient and control groups are analyzed using the GWAS approach to identify probable causal candidate(s) in PK and/or PD genes. Functional details of these candidates need to be established and clinically validated before any clinical guidelines can be implemented.

2012). Such an “off target” effect may also be induced by a variant in a pharmacogene, which although itself is not involved in direct interaction with the drug, is a member gene of the drug metabolizing pathway.

In general, pharmacogenetic variability can be broadly classified into three groups:

1. Inherited Mendelian monogenic traits, disorders, or ADRs that are affected by usually single rare coding variants;
2. Oligogenic traits affected by a few PK and/or PD genes; and
3. Complex multifactorial traits affected by not only many small-effect pharmacogenetic variants but possibly also epigenetic and environmental factors (Zhang and Nebert, 2017).

The complexity in predicting and identifying the three categories of pharmacogenetics increases as the number of genes and factors increases, ranging from simple statistical association between genotypes and pharmacological phenotypes to massive whole genome- or exome-wide association studies.

Workflow in Pharmacogenetics

Increasingly, pharmacogenomics research involving large number of patients across different population groups is believed to hold the key to the resolution of low pharmacological efficacy observed in many of today’s drug treatments. Identification of pharmacogenetic variants usually adopts either the candidate gene or genome-wide approach. The former involves genotyping of either one or a few (sometimes up to hundreds of) genes using techniques ranging from PCR or SNP array to targeted next-generation sequencing (NGS). This is a workable approach when prior functional knowledge of the pharmacogenes and their related diseases or phenotypes is known. The latter, which sometimes is also known as the hypothesis-generating approach, uses various NGS methodologies to screen for genetic variants that include single-nucleotide variants (SNVs), insertion/deletions (indels), and structural variants (SVs) in the entire genome of patient (e.g., drug responders, ADR patients) and control (e.g., nonresponder, extensive, or normal drug metabolizers) groups (Fig. 1). No prior knowledge about any of the genetic variants is necessary for this approach. Although discovery in nature, the genome-wide approach is especially useful for studying complex traits/diseases that are influenced by multiple genetic factors. Compared with the candidate gene approach, this latter approach allows the systematic testing of more hypotheses in order to discover novel associations. Discussion on the advantages and disadvantages of the two approaches and the technologies involved is provided elsewhere (Peters et al., 2010; Yang et al., 2016; Cohn et al., 2017).

NGS technologies have the potential to discover millions of genetic variants in both diseased and healthy control individuals. Characterization of the effects of these variants on drug response forms the main objective of pharmacogenetic/-genomic studies. Whilst the number of methods and tools available for the analysis of genetic variants are too many to be adequately reviewed

Fig. 2 A workflow of pharmacogenetics GWAS. True causal candidate variants identified during initial GWAS analysis are usually difficult to distinguish as they cluster with neutral variants in LD. They may also be missing from the list. Fine-mapping process, including filling in the variant gaps using imputation tools, is necessary to refine this list. Functional annotation and studies are next performed to decipher the biological mechanisms behind the association of the variants and drug response.

here (Omick, 2018; Henry *et al.*, 2014), some basic steps illustrated in Fig. 2 are commonly adopted, especially for the genome-wide approach.

In the last decade, genome-wide association studies (GWAS) have been widely and successfully used in the identification of single-nucleotide polymorphisms (SNPs) in genes that are associated with a variety of human phenotypes or traits, including that of pharmacogenetic significance (Cooper *et al.*, 2008; Takeuchi *et al.*, 2009; Giacomini *et al.*, 2017). A total of 333 entries on SNP-trait associations for “Response to drug” are now held in the GWAS Catalog (MacArthur *et al.*, 2017).

Statistically, GWAS analysis is basically a straightforward null hypothesis test to identify variant data that lies at the far ends of the null distribution. These are the SNPs in which associations with the tested pharmacological outcome are considered statistically significant. A few factors should be taken into consideration when a pharmacogenomics GWAS is planned. They include the allelic frequency of the SNPs, effect size (small- or large-) of SNPs on the phenotypes, the need of large sample sizes or cohorts to provide the necessary statistical power to identify the candidate SNPs, characteristics (*e.g.*, treatment regimen, patient features such as ethnicity, etc.) of the population studied, and study design (either observational study or randomized controlled trial) (Motsinger-Reif *et al.*, 2013). Furthermore, it is also important to realize that pharmacogenomics GWAS may differ from most other diseased traits in such a way that (1) due to the presence of clinically well-defined phenotypes with known underlying mechanisms, the pharmacogenomic outcomes are often clear; and (2) association can be established with greater statistical confidence since larger genetic effects may exist in some of the pharmacogenomic phenotypes.

Although many tools have been developed over the years to deal with different forms of GWAS data, some widely used analytical features include distribution of allelic frequencies, Hardy-Weinberg equilibrium, analysis of association between single SNPs and haplotypes with different traits, etc. The results of GWAS analyses are typically presented in a graph as either a QQ or a Manhattan plot of *P*-values representing the association test of each genetic variant across a chromosomal region (Uitterlinden, 2016; Reed *et al.*, 2015).

However, one of the biggest drawbacks of GWAS analysis, including that for pharmacogenomics, is the large number of resulting candidate genetic variants; many of which are clustered in linkage disequilibrium (LD) in the implicated loci. Here, the haplotype structure of these loci makes the distinction between neutral and causal variants difficult (Spain and Barrett, 2015). In addition, rarely do any of the GWAS variants fall within protein-coding sequences. Instead, the vast majority of them are found in the noncoding segments of the human genome where functional details may be incomplete or lacking (Farh *et al.*, 2015); despite efforts such as ENCODE (Encode_Project Consortium, 2011) and Fantom5 (Kawaji *et al.*, 2017) to annotate these regulatory regions. As a result, direct translation of GWAS variants into targetable pharmacogenetic markers is not always possible and further refinement of the list of candidate variants using methods such as fine-mapping and/or genotype is necessary.

In essence, fine-mapping aims to pinpoint the causal variants and/or genes that statistically are most likely to have a direct effect on the observed phenotype. However, before this can be done, many of the common variants in the loci should be genotyped or imputed with high confidence. This is especially important with GWAS summary data derived from medium- to low-coverage genotyping or whole genome sequencing datasets (Chan *et al.*, 2016). Using comprehensive genotype data such as the 1000 Genomes Project reference panels (1000_Genomes_Project Consortium *et al.*, 2012), imputation allows variant gaps missing from the genotyping arrays or NGS to be filled in. This much improved dataset can then undergo either a step-wise conditional analysis in which SNPs with the lowest *P*-value or LD are conditioned iteratively till no more SNP is found to reach the threshold of the preassigned *P*-value or analysis using Bayesian methods to assign each of the SNPs with posterior probabilities of causality (Spain and Barrett, 2015).

However, the value of a GWAS/fine-mapping exercise is not fully realized until the underlying functional basis of the refined causal genetic variants and/or the target gene can be resolved with informed biological inference through some post-GWAS analysis. Among them are expression quantitative trait loci analysis, which attempts to correlate genetic variants on regulatory regions with quantitative changes in the expression of genes that are under the control of affected elements (Schroder *et al.*, 2013; GTEx Consortium, 2015); genome-wide gene enrichment and pathway analysis to link a trait or phenotype to a pathway(s) instead of looking at single genes only (Postmus *et al.*, 2014; Di Iulio and Rotger, 2011); and protein-protein interaction analysis to predict drug repurposing (Pritchard *et al.*, 2017).

Both *in vitro* and *in vivo* assays can subsequently be run to validate and characterize the predicted functional mechanisms and roles of the candidate causal variants in the drug response. Clinical studies are finally done before any such variants can be confidently established as a pharmacogenetics marker in the population.

Some of the major bioinformatics tools used in the pharmacogenomics workflow outlined above are described in the next section.

Bioinformatics Resources for Pharmacogenetics/-Genomics

Bioinformatics Analysis Tools

GWAS are currently seen as one of the best methodologies for population analysis of pharmacogenetic polymorphisms. Advances in NGS technologies and the accompanying bioinformatics tools have allowed GWAS to be conducted with higher statistically precision. It is therefore not unexpected that nearly 500 tools have been developed to analyze various aspects of GWAS (Omicx, 2018). A few of the widely used ones are discussed below.

General GWAS analysis

PLINK: A free open-source whole genome GWAS toolset capable of performing analyses ranging from the very basic to the large-scale computationally demanding ones (Chang *et al.*, 2015; Purcell *et al.*, 2007). PLINK does not do any pre-GWAS analysis, such as genotype or CNV calling. It is a pure genotype/phenotype analytical tool with support for visualization, annotation, and management of results.

GenABEL: A software package based on the R statistical programming language; it is used for the statistical analyses of genome variation data (Aulchenko *et al.*, 2007). It contains subprograms to do genome-wide association (GWA) analysis (GenABEL, ProbABEL, MixABEL, OmicABEL), meta-analysis (MetABEL), parallelization of GWA analyses (ParallABEL), management of very large files (DatABEL), and evaluation of prediction (PredictABEL). It also provides tools for visualizing the statistical output.

Bioconductor: Another R open-source and open development effort to provide a comprehensive collection of tools to analyze different types of high-throughput genomic data (*e.g.*, microarray, NGS genotypes) (Huber *et al.*, 2015). A number of R programs are included in Bioconductor to deal with association studies, including GWASTools (Gogarten *et al.*, 2012) and traseR (Chen and Qin, 2016).

Imputation

IMPUTE: The program or its latest version IMPUTE2 is a tool used for genotype imputation and phasing in GWAS/fine-mapping studies. It is based on dense marker sets such as haplotypes from the 1000 Genomes Project (Howie *et al.*, 2009). IMPUTE2 can achieve a higher accuracy and allow information across multiple reference panels to be combined while remaining computationally feasible.

BEAGLE: A software package that performs “genotype calling, genotype phasing, imputation of ungenotyped markers, and identity-by-descent segment detection” (Browning and Browning, 2016; Browning and Browning, 2007). It is capable of analyzing big genetic datasets containing hundreds of thousands of genotypes on thousands of samples.

MACH: The core function of this package is to perform genotype imputation and haplotype phasing in samples of unrelated individuals within a variety of populations (Li *et al.*, 2010). The software achieves this by using the HapMap sample or other densely genotyped individuals (*e.g.*, from the 1000 Genomes Project) as a reference. Simple tests of association can also be run using MACH.

Functional annotation of variants

Variant Effect Predictor: A powerful toolset developed by ENSEMBL to analyze, annotate, and prioritize genomic variants (SNPs, insertions, deletions, CNVs, or SVs) in both coding and noncoding regions (McLaren *et al.*, 2016).

SnEff: A toolbox containing different programs to annotate and predict the effects of genetic variants on genes and proteins (Cingolani *et al.*, 2012). It also allows annotation using the GWAS catalog (Nhgri-Ebi, 2018).

ANNOVAR: A tool to efficiently annotate genetic variants (SNVs and indels) (Wang *et al.*, 2010). Using update-to-date information, it assigns “functional consequences of genes, inferring cytogenetic bands, reporting functional importance scores, finding variants in conserved regions, or identifying variants reported in the 1000 Genomes Project and dbSNP.”

Databases

For a long time, genetic variants associated with drug response have been deposited together with other data in various large-scale databases such as the dbSNP of NCBI and European Genome-Phenome Archive of EBI. However, the ever-increasing genetic and genomic data generated from population-wide sequencing and GWAS studies has seen the growth of dedicated pharmacogenomics-centric web resources. Some of these have been reviewed elsewhere (Zhang *et al.*, 2015; Potamias *et al.*, 2014; Sim *et al.*, 2011) and a few of the prominent ones are discussed here (Table 1).

PharmGKB (The Pharmacogenomics Knowledge Base) is a curated knowledge base providing organized information on the impacts of human genetic variations on drug response. It currently holds annotation for about 19,000 genetic variants (SNP, indel, repeat, haplotype). They are integrated into nearly 3500 genotype-phenotype relationships; 500 clinical prescriptions in the form of drug labelings, 98 genotype-based dosing recommendations, and 128 pathways showing the association of genotypes with PK

Table 1 Web-based Databases of Pharmacogenomics

Database (url)	Features	Reference
PharmGKB The Pharmacogenomics Knowledge base (https://www.pharmgkb.org/)	A curated knowledge base providing organized information on the impacts of human genetic variations on drug response. Among the vast resources, the database also contains clinical prescribing information detailing gene–drug associations, genotype–phenotype relationships, and dosing guidelines.	Whirl-Carrillo <i>et al.</i> (2012)
PharmVar Pharmacogene Variation Consortium (https://www.pharmvar.org/)	A central repository of haplotype structure and allelic variants of pharmacogenes. The database is a transition from the CYP-allele Database (http://www.cypalleles.ki.se/), which contains the nomenclature of human <i>CYP450</i> alleles.	Gaedigk <i>et al.</i> (2018); Sim <i>et al.</i> (2010)
DrugBank (https://www.drugbank.ca/)	A comprehensive bioinformatics and cheminformatics database containing information on drugs and drug targets. It also contains resources on pharmaco-genomics, -metabolomics, -transcriptomics, and -proteomics.	Wishart <i>et al.</i> (2018, 2006)
CPIC The Clinical Pharmacogenetics Implementation Consortium (https://cpicpgx.org/)	A detailed collection of regularly updated, peer-reviewed, and evidence-based clinical practice guidelines to facilitate the implementation of pharmacogenetic tests for patient care.	Relling and Klein (2011), Caudle <i>et al.</i> (2014)
SPHINX Sequence and Phenotype Integration Exchange (https://www.emergesphinx.org/)	A searchable catalog of inherited variants found in 82 important pharmacogenes of a large population cohort. In addition to the lists of genes, drugs, and pathways, SPHINX also contains such information as the implication of the genetic variations, drug interactions, and allelic frequencies of variants.	Rasmussen-Torvik, <i>et al.</i> (2014)
ePGA electronic Pharmacogenomics Assistant (http://www.epga.gr/)	A collection of public datasets linking the interactions between drug metabolizing status and the related haplotype information. The genotype-to-phenotype translation tool matches individual genotype profiles with known pharmacogenetics variation to give an indicative drug efficacy/toxicity summary.	Lakiotaki <i>et al.</i> (2016)
FDA Pharmacogenomic Biomarkers (https://www.fda.gov/Drugs/ScienceResearch/ucm572698.htm)	A table listing the pharmacogenomic biomarkers of FDA-approved drugs. Information includes clinical response, drug exposure variability, and dosing recommendation due either to germline or somatic variants of the pharmacogenes.	
PharmaADME Pharmacogenetics of Absorption, Distribution, Metabolism & Excretion genes (http://pharmaadme.org/)	An industry–academia effort that provides lists of standardized “evidence based” pharmacogenetics biomarkers that affect the absorption, distribution, metabolism, and excretion of drugs.	
PhID Pharmacology Interactions Database (http://phid.ditad.org/)	A database that allows visualization of complex network relationships among diseases, targets, drugs, genes, side effects, and pathways.	Deng <i>et al.</i> (2017)
GPCRdb G protein-coupled receptors (GPCRs) Database (http://gpcrdb.org/)	A comprehensive database containing data on genes, proteins, tertiary structures, ligand-receptors, and drug targets of GPCRs. The site also provides tools to select and study the impact of natural genetic variation for the drug targets of GPCRs.	Isberg <i>et al.</i> (2016), Hauser <i>et al.</i> (2018)
The NATs database The database of arylamine N-acetyltransferases (NATs) (http://nat.mbg.duth.gr/)	This database set up by The <i>NAT</i> Gene Nomenclature Committee covers the nomenclature and alleles of the polymorphic phase II xenobiotic metabolizing enzymes, arylamine NATs, from both eukaryotes, including those from the human, and prokaryotes.	Hein, <i>et al.</i> (2008)
PMT database The Pharmacogenetics of Membrane Transporters (http://pharmacogenetics.ucsf.edu/)	A database that provides information on both coding and noncoding genetic variants of solute carrier (SLC) transporters and ATP-binding cassette (ABC) transporters. Locations of the variants on the gene and secondary protein structure are also mapped. In addition, allelic frequencies in major racial and ethnic populations are also given.	Kroetz <i>et al.</i> (2010)
UGT-allele database The UDP-glucuronosyltransferase Allele Nomenclature (https://www.pharmacogenomics.pha.ulaval.ca/ugt-alleles-nomenclature/)	A catalogue of human <i>UGT1A</i> and <i>UGT2B</i> haplotypes and SNPs. Information of pharmacogenetic relevance include allelic names, nucleotide changes, protein effects, genotype–phenotypes.	Mackenzie <i>et al.</i> (2005)

and PD of drugs; and 64 Very Important Pharmacogenes (VIP) where there is considerable evidence on the pharmacogenomics of each of the genes.

PharmVar (Pharmacogene Variation Consortium) is a central repository of haplotype structure and allelic variants of pharmacogenes. This updated database is a transition from the Human Cytochrome P450 (CYP) Allele Nomenclature Database (Table 1), which housed the nomenclature and genotypes of the human CYP450 alleles.

DrugBank is a comprehensive bioinformatics and cheminformatics database that encompasses information such as PK, PD, ADRs, ADEMT, etc., of drugs and drug targets. In addition, it also contains multiomics (pharmacogenomics, -metabonomics, -transcriptomics and -proteomics) resources on the drug-gene interactions.

CPIC (*The Clinical Pharmacogenetics Implementation Consortium*) is a consortial effort to address the difficulty in translating pharmacogenetic findings into actionable prescribing information for clinicians. The database provides detailed collection of regularly updated, peer-reviewed, and evidence-based clinical practice guidelines to facilitate the implementation of pharmacogenetic tests for patient care. A total of 34 guidelines and updates have been published to date (January 2018).

SPHINX (*Sequence and Phenotype Integration Exchange*) is a searchable catalogue of inherited variants in 82 very important pharmacogenes identified from large population studies. In addition, the database also contains such information as the implication of the genetic variations, drug interactions, allelic frequencies of variants, and pathways of metabolism and diseases.

ePGA (*electronic Pharmacogenomics Assistant*) is a collection of public datasets used to provide associations between the haplotypes/alleles and possible ADME reactions. The genotype-to-phenotype translation tool matches individual genotype profiles with known pharmacogenetics variation to give an indicative drug efficacy/toxicity summary.

FDA Pharmacogenomic Biomarkers is a table listing FDA-approved drugs with labelings containing information on the associated pharmacogenomic biomarkers. Other information on the labeling includes clinical response, drug exposure variability, and dosing recommendation due either to germline or somatic variants of pharmacogenes.

e-PKGene integrates information from different resources to allow quantitative analysis of how genetic variants of drug metabolizing enzymes and transporters impact on pharmacokinetic responses to drugs and metabolites. Where available, summaries of the impact of variants on drugs and metabolites in different populations are also provided.

PharmaADME (*Pharmacogenetics of Absorption, Distribution, Metabolism & Excretion genes*) is an industry-academia effort that provides a consensus core list of standardized "evidence based" pharmacogenetic biomarkers that have been shown to affect the absorption, distribution, metabolism, and excretion of drugs.

PhID (*Pharmacology Interactions Database*) is a database that allows visualization of complex network relationships among diseases, targets, drugs, genes, side effects, and pathways.

SuperCYP is a Cytochrome P450 database containing genetic variants of CYP450 genes. The site also provide a tool to analyze interactions between CYP450 enzymes and drugs.

GPCRdb (*GPCRs Database*) is a comprehensive database containing data on genes, proteins, tertiary structures, ligand-receptor, and drug targets of GPCRs. The site also provides tools to select and study the impact of natural genetic variation for the drug targets of GPCRs.

The NATs database (*The database of arylamine N-acetyltransferases (NATs)*), set up by the NAT Gene Nomenclature Committee, covers the nomenclature and alleles of the polymorphic phase II xenobiotic metabolizing enzymes, arylamine NATs, from both eukaryotes, including those from the human, and prokaryotes.

PMT database (*the Pharmacogenetics of Membrane Transporters*) provides information on both coding and noncoding genetic variants of SLC transporters and ABC transporters. Locations of the variants on the gene and secondary protein structure are also mapped. In addition, allelic frequencies in major ethnic population groups are also given.

UGT-allele database (*The UDP-glucuronosyltransferase Allele Nomenclature*) is a catalogue of human UGT1A and UGT2B haplotypes and SNPs. Information of pharmacogenetic relevance includes allelic names, nucleotide changes, protein effects, genotype-phenotypes.

Pharmacogenetics in Practice

Although clinical implementation of pharmacogenomics is yet to be fully realized, there have been some success stories thus far. To date, the Clinical Pharmacogenetics Implementation Consortium has issued detailed practical guidelines for the application of pharmacogenetics in the therapeutic usage of 35 drugs (Relling and Klein, 2011; Drew, 2016). Among them is the genotyping of the highly variable major histocompatibility complex class I allele (HLA) (Becquemont, 2010) for abacavir (Watson *et al.*, 2009; Young *et al.*, 2008), carbamazepine (Phillips *et al.*, 2018), and allopurinol (Saito *et al.*, 2016; Hershfield *et al.*, 2013); the drugs prescribed for the treatment of HIV, epilepsy, and gout respectively. Approximately 5%–8% Caucasian and 0.26%–3.6% African American, Asian, and Hispanic HIV/AIDS patients with the HLA-B*57:01 allele are affected by the abacavir hypersensitivity syndrome during the first 6 weeks of drug administration (Ma *et al.*, 2010). Screening for this allele prior to drug therapy is therefore recommended by various healthcare authorities worldwide (Martin *et al.*, 2012). On the other hand, patients harboring the HLA-B*15:02 pharmacogenetic marker of Southeast Asian and Chinese origin are known to suffer from severe and potentially fatal carbamazepine-induced cutaneous adverse reactions such as toxic epidermal necrolysis (TEN) and Stevens–Johnson syndrome (SJS). This allele is present in approximately 10%–15% of the population groups in this region but <1% in the Japanese and Korean population; and it is largely absent in other non-Asian population groups (Chung *et al.*, 2004; Hung *et al.*, 2006; Kaniwa *et al.*, 2013). Similarly, allopurinol-induced TEN/SJS is more prevalent in Taiwanese and Southeast Asian patients with the HLA-B*58:01 allele (Hung *et al.*, 2005; Tassaneeyakul *et al.*, 2009).

It is estimated that almost 60%–70% of all breast cancers are estrogen receptor (ER)-positive and therefore, inhibitors of ER signaling, such as tamoxifen (TAM), remain as one of the most widely prescribed drug treatment options for patients (Hertz *et al.*, 2017). TAM has been shown to reduce the recurrence and mortality rates by one third in both pre- and postmenopausal women (Goetz *et al.*, 2008). However, approximately 40% of patients are unresponsive to the treatment due to interindividual genetic

variability (Hertz *et al.*, 2017). The highly polymorphic drug metabolizing gene *CYP2D6* (with > 160 alleles (Gaedigk *et al.*, 2018; Pharmgkb, 2017) has been implicated in this unsatisfactory treatment outcome (Rofaie *et al.*, 2010). For instance, *CYP2D6**10 allele, which corresponds to a decreased enzyme activity and intermediate drug metabolism, is more prevalent amongst Asians and Africans; with the phenotype amounting to about 38%–70% (Rofaie *et al.*, 2010). On the hand, the allele *CYP2D6**4, which corresponds to a nonfunctional variant and hence a poor metabolism (PM) phenotype, is more prevalent amongst Caucasians (Fernandez-Santander *et al.*, 2013) than Asians (Lim *et al.*, 2011). Due to its obvious medical benefit, the US FDA has in fact approved pharmacogenetic testings for *CYP2D6* variants prior to treatment with tamoxifen (Rofaie *et al.*, 2010).

In addition, pharmacogenomics research on a number of other drugs are currently undertaken by various large international consortia (Giacomini *et al.*, 2017). Translation of such efforts into more pharmacogenomic guidelines and clinical implementation should further expand the success stories.

Conclusions

The ability to interrogate genetic variation at a population scale over the last decade has seen a rapid paradigm shift in medicine, in particular the field of drug treatment, from the “one size fits all” approach to a more targeted and precise treatment tailored according to an individual’s genetic and genomic profile. Although most patients have been shown to harbor at least one actionable pharmacogenetic variant (Van Driest *et al.*, 2014), clinical prediction of drug response due to these genotypes has only been applied to relatively few drugs, which exclude even many of the most commonly prescribed ones (Relling and Evans, 2015; Caudle *et al.*, 2014; Janssens and Van Duijn, 2008). In most of these cases, pharmacogenetic guidelines are only provided to drugs whereby a small number of large-effect contributing genetic variants can be confidently associated with a clearly defined set of phenotypes such as efficacy effects and ADRs.

Pharmacogenetic association between drugs and complex traits, such as type 2 diabetes (Florez, 2017) and irritable bowel syndrome (Rufini *et al.*, 2017), usually involves multiple genetic factors and accurate deciphering of such relationship remains challenging. Not only are the genotype–phenotype association marginal in many of the complex diseases, some pharmacogenetic variants also work in combination to exert their effects (Zhang and Nebert, 2017). In addition, many of pharmacological phenotypes can further be complicated by changes in gene expression (Gamazon *et al.*, 2010), epigenetic regulation (Cacabelos and Torrellas, 2015; Pisanu *et al.*, 2018), and protein–protein interactions (Shiota *et al.*, 2008) brought about by genetic variation in either the pharmacogenes or their associated pathway genes.

Although advances in NGS and GWAS technologies have enabled many more pharmacogenetic variants to be identified through the running of large-scale cohort studies and some even at a whole-nation level (Gudbjartsson *et al.*, 2015), this deluge of data is also accompanied by increases in biases and noise of the data. Therefore, improved computational methodologies that are capable of handling veracity of big genomic data are needed.

More importantly, variants identified in many of these large sample size studies are not always going to benefit pharmacogenomic GWAS due to the simple fact that the prevalence, and hence the availability, of large sample size is usually not possible with multidrugs induced diseases having clear defined adverse pharmacological phenotypes. This much needed statistical resolution provided by the sample size is further reduced when the interethnic genetic variation is also taken into consideration. Although some progresses have recently been made to provide a glimpse into the pharmacogenomics of various population groups across the world (Ramos *et al.*, 2014; Giacomini *et al.*, 2017), the number of individuals with ADRs sequenced within each of the different ethnic groups remains small. The trend of sequencing and fine-mapping of genetic variants in other non-European and ancestral populations is, therefore, expected to continue. Technologies such as improved GWAS, as well as whole genome and exome NGS, will aid in better translation of ethnicity-specific pharmacogenetic/-genomic findings into clinical practice (Chan *et al.*, 2015; Popejoy and Fullerton, 2016).

The field of pharmacogenomics is developing rapidly. However, continuous national-scale genotyping of population groups and whole genome/exome GWAS alone are not likely to result in widespread clinical application of pharmacogenomics. Further technological and methodological advancement in areas such as long read sequencing, imputation, and precision fine-mapping are needed to increase the quantity and quality of the pharmacogenomics variants. Coupled with a more integrated approach encompassing multiomics system biology, healthcare records, and artificial intelligence, pharmacogenomic data derived from population-wide analysis is expected to ultimately speed up the introduction of stratified, if not personalized, drug treatment in the near future.

Introduction

For the past decade, genome-wide association studies (GWASes) have been the focus of large-scale genetic studies that are used to characterize the genomic architecture of traits and diseases (Visscher *et al.*, 2012). These GWASes have been largely brought about by the use of single nucleotide polymorphism (SNP) microarrays, coupled with a wealth of computational tools to efficiently process and analyze the high throughput data on a large scale. SNP arrays have enabled the easy genotyping of millions of variants in the genomes of hundreds of individuals (International HapMap Consortium *et al.*, 2007; The International HapMap 3 Consortium, 2010). As they typically need to know the sequence of these genomic locations to design the array probes, the variants detected are mainly common polymorphisms, which are defined to be at a minor allele frequency (MAF) of at least 5% in the human population. In general, less common polymorphisms are between MAF 1% and 5%, and rare variants are variation that occur with MAF of less than 1% in the human population.

As of 2016, the GWAS catalog from the National Human Genome Research Institute (NHGRI) houses published GWASes from about 2500 publications, for over 24000 SNP-trait associations (MacArthur *et al.*, 2017). Despite this large number of trait and disease associations with common variants, much of the genetic contributions to these traits and diseases remain unexplained. Due to the initial focus on the common variants, variants with lower MAF in the human population have been thought to account for at least part of this “missing heritability” (Zuk *et al.*, 2014). The 1000 Genomes Project sequenced 2504 healthy individuals from 26 ethnic populations. They found that while rare variation comprises only 5% of the total variation per individual, collectively, rare germline variants are in abundance in the general human population (1000 Genomes Project Consortium *et al.*, 2015, 2012). Previously, rare variants have already been shown to play significant roles in human diseases and traits. Highly penetrant rare variants are known to cause Mendelian disorders; such as, cystic fibrosis (Castaldo *et al.*, 1999; Soe and Gregoire-Bottex, 2017) and sickle cell anemia (Higgs and Wood, 2008); and common (and complex) diseases; such as, autism (Griswold *et al.*, 2015) and Type 2 Diabetes (Steinthorsdottir *et al.*, 2014). There is, however, an ascertainment bias that partially hindered the research of rare variants. This bias is largely due to the difficulty in detecting and identifying these variants for genotyping probe creation in microarrays, coupled with the appeal of finding and publishing the “low-hanging fruits” in association studies; that is, the associations of traits with more easily detected common variants. For these reasons, the community have, for a while, largely neglected this lower end of the allele frequency spectrum.

In more recent years, the advent and maturation of short-read DNA sequencing technologies have engendered the sequencing of entire genomes of thousands of individuals that can be interrogated multiple times (more deeply). Consequently, rare genomic variants can now be detected per individual more easily. An entire ecosystem of bioinformatic algorithms have also been developed to meet the challenges of automation, and facilitating the procedures of data collection, processing, visualization, and computational analyses. In this article, we will introduce a non-exhaustive array of ways that bioinformatics and computational biology have been harnessed to create tools and methodologies, specifically in detecting and annotating rare variation.

Detection of Rare Variation

Over the years, there has been evolving connotations and meanings of the use of terminologies to define ‘nucleotide changes’, such as ‘mutation’ and ‘polymorphism’ (Condit *et al.*, 2002; Karki *et al.*, 2015). This created confusion depending on the context such as the effect (disease-causing or neutral), allelic frequency (rare or polymorphic), and inheritance pattern (somatic or germline). In order to prevent further confusion, the American College of Medical Genetics and Genomics (ACMG), the Human Variome Project, the Human Genome Variation Society (HGVS) and the Human Genome Organization (HUGO) have published recommendations and guidelines in favor of the use of more neutral terms such as ‘variant’, ‘alteration’, and ‘allelic variant’, to refer more generically to nucleotide changes in the genome, which include both natural variations and mutations (Richards *et al.*, 2015; den Dunnen *et al.*, 2016; Li *et al.*, 2017). Henceforth, we will be referring to any generic nucleotide change as a ‘variant’.

Broadly, there are three types of variants in the human genome. These are single nucleotide substitutions (SNVs), small insertions/deletions (indels) of nucleotides, and structural variants that comprise translocation and/or inversion of long chunks of DNA sequences (SVs). In addition, SVs may cause amplification or loss of large chunks of DNA sequences. These are referred to as copy number variants (CNVs). Each variant type is then detected (or “called”) using different bioinformatics methodologies. While the computational tools for the detection of rare variants are mostly generic variant calling methodologies for arrays and sequencing technologies, they have to be customized with appropriate considerations to cater to the specific underlying array and sequencing technologies, in order to more accurately detect variants with lower frequencies. Additionally, the use of *in silico* genotype imputation has also been proven to be extremely accurate in many instances, and thus provides a more cost-effective complement to array, and targeted and exome sequencing options. Hence, we will first review some of the challenges and strategies

in rare variant detection. We will then discuss, in turn, the application of bioinformatics in microarray, sequencing and imputation technologies. Finally, there are non-germline variants that are also rare, for instance, somatic mutations. Hence, we include a section on somatic mutation calling in cancer research.

Challenges and Strategies in Rare Variant Detection

Rare variants occur in very low frequency in the population. Various human genetics efforts have defined the threshold of rarity slightly differently. For example, the 1000 Genomes Project defines $<0.5\%$ to be rare ([The 1000 Genomes Project Consortium, 2012, 2015](#)), while others have used $<1\%$ as the threshold ([Agarwala et al., 2013](#); [Chouraki and Seshadri, 2014](#); [Bomba et al., 2017](#)). The low occurrence of these variants in the population is, in itself, a challenge that initially hampered the high throughput detection of rare and novel variants using genotyping arrays. The advent of sequencing enabled *de novo* rare variant detection on a large scale. In order to detect rare variants, population scale sequencing is typically performed, followed by using efficient bioinformatic pipelines to pool all the sequenced reads and perform variant calling on the pooled data. In this approach, the sequencing errors (such as polymerase chain reaction amplifications) do not affect the variant calling because they are mostly independent between individuals, and using pooled data alleviates the severity of these errors. The computational tools for the pooled variant calling procedure are parametrized to have high sensitivity. Thus, pooled variant calling increases power to detect rare variants that have very low frequencies, and also help decrease the false positive rates of detection ([1000 Genomes Project Consortium et al., 2015](#)). The cost of sequencing can be decreased by performing a low coverage sequencing in each individual. This may, however, come at the cost of reduced power to detect rare variants.

In many cases, in order to circumvent the issue of cost and coverage, it may be useful to perform targeted sequencing; for example, exome sequencing. In such a way, the cost is decreased but only a particular region or regions of interest are sequenced; using the example of exome sequencing, only the exons are sequenced. This approach increases the power to detect variants (e.g., on the exons) by trading read depth coverage for genomic coverage. One downside of this approach is that the target capture technologies have non-uniform efficiency among different parts of the genome, for example, across different exons ([Wang et al., 2017](#); [Clark et al., 2011](#)). This causes non-uniform genomic coverage, and complicates computational detection of some variants, such as in the detection of CNVs, which look for duplication or deleted regions ([Wu et al., 2012](#)). This approach is also not easily applicable for identifying complex SVs because of the low concordance between different methodologies and high false positive error rates. However, some studies have found that whole genome sequencing is less biased in identifying variants than exome sequencing ([Belkadi et al., 2015](#)).

An important aspect of detecting rare variants is also the characterization of low frequency haplotypes in the human genome. In order to identify rare haplotypes, it is necessary to have deeply catalogued population-specific genetic panels. Using these panels, the bioinformatics pipelines for variant calling can be combined with genetic imputation to detect rare variants more accurately (please refer to Section ‘Genotype Imputation’). This greatly depends on our ability to build high quality population panels ([The International HapMap 3 Consortium, 2010](#)). Also, this approach may not work well for SVs and CNVs. CNVs do not correlate highly with other variants in the linkage disequilibrium blocks. For complex SVs, the understanding of their recombination rates and LD block is not yet very well-developed ([Wineinger et al., 2011](#)). Altogether, these render the imputation of SV and CNV genotypes less accurate than SNVs and indels.

Nonetheless, the use of sequencing technologies has spurred complementary strategies in microarrays, targeted sequencing and imputation to detect rare variants.

Microarrays

Microarrays require the knowledge of the genomic sequences for probe design. Hence, the initial microarrays for variant detection were more catered for common variants. With next-generation sequencing (NGS) efforts in obtaining rare variant sequences, many arrays have incorporated rare variant probes detected from NGS. This is also implemented in a more targeted, and context-specific manner, such as focusing on certain diseases, ethnicities or genomic regions. For example, bespoke customized genotyping arrays such as the Immunochip ([Cortes and Brown, 2011](#)), Illumina ExomeChip ([Illumina, URL available in references](#)), and the UK Biobank Axiom Array ([Affymetrix, URL available in references](#)) have probes that are specially designed for rare single nucleotide variants in different contexts. For larger SVs, the array comparative genomic hybridization technology ([Banerjee, 2013](#)) and the more recent SNP arrays from Illumina and Affymetrix have been used for detection of rare CNVs or SVs. These custom-built microarray chips allow for a cheaper and more focused option for the detection of rare variants. Moreover, rare variant detection in microarrays can conveniently capitalize on the bioinformatics methods and tools made for microarrays that have been well-characterized, and -utilized for almost two decades ([LaFramboise, 2009](#)).

In microarray data, preprocessing of the signal intensities from the probes consists of multiple steps, and needs to be executed before genotype calling. These include *in silico* background correction, resulting from technical artefacts such as non-specific probe hybridization ([Owzar et al., 2008](#)); normalization of the probes intensities, within and between chips, so that intensities can be compared across all chips ([Carvalho et al., 2007](#); [Hu and He, 2007](#); [Staaf et al., 2008](#)); removal of batch effects ([Miclous et al., 2010](#)); quality control and outlier removal ([Guo et al., 2014](#)). There are bioinformatics tools that implement statistical methods for these preprocessing steps. For example, Robust Multiarray Analysis (RMA) uses parametric background correction, quantile

normalization and robust fitting of a log-linear additive model (Irizarry *et al.*, 2003). There are also R packages conveniently available in Bioconductor (Huber *et al.*, 2015) streamlined for analyses in R (Morgan, 2016; Gentleman *et al.*, 2005). Following preprocessing, genotype calling tools can be implemented for clustering to call genotypes. These have included open source tools from academia (Teo, 2012; Wellcome Trust Case Control Consortium, 2007; Wang *et al.*, 2007), and proprietary software from companies such as BeadStudio, and Affymetrix clustering algorithms for different microarray platforms.

Exome/Whole Genome Sequencing

For variant detection in NGS technologies, the reads from sequencing experiments are mapped on the reference genome using short read mapping tools like BWA (Li *et al.*, 2008) and Bowtie (Langmead and Salzberg, 2012). In SNV detection, the SNVs are detected by finding the single nucleotide differences in the mapped reads compared to the reference genome (Fig. 1). Indels are detected by comparing the reference genome and the mapped reads to identify the insertions/deletions of nucleotides in the mapped reads (Fig. 1). The identification of SVs (and CNVs) requires detection of the breakpoints that correspond to DNA positions that formed the SVs. The mapped reads are analyzed to find breakpoints at the ends of SVs (Fig. 1). Currently, analysis of the paired end reads and fine mapping of breakpoints by splitting, and mapping the reads (split read mapping) are the most reliable ways to identify SVs. Finally, an SV is identified by careful analysis of mapping patterns of paired-end reads. These strategies are utilized by bioinformatics algorithms for detecting SVs, such as DELLY, PEMer, BreakDancer, and GenomeStrip (Rausch *et al.*, 2012; Korbel *et al.*, 2009; Alkan *et al.*, 2011; Handsaker *et al.*, 2011; Chen *et al.*, 2009). For the SVs that amplify and delete chunks of DNA, i.e., CNVs, analysis of the read depth has been successful, which is used by CNVnator to detect CNVs (Abyzov *et al.*, 2011).

The sensitivity of bioinformatics tools for variant detection is variable among different types of variants. Sensitivity of SNV detection using short read sequencing technologies is very high (1000 Genomes Project Consortium *et al.*, 2012, 2015). GATK (McKenna *et al.*, 2010) is currently the standard bioinformatics tool that is used for detecting SNVs. VarScan (Koboldt *et al.*, 2009) is another popular variant detection tool. The combination of the software packages GATK and dindel (Albers *et al.*, 2011) has been used in indel detection. The sensitivity of indel detection is high, albeit the false positive rates can be high as well (Hasan *et al.*, 2015). The accuracy of SV detection is hard to quantify as they differ depending on contexts, such as in diseased and normal individuals. This is mainly because there are currently no appropriate ground-truth references for SVs. Nonetheless, large-scale projects like the 1000 Genomes (1000 Genomes Project Consortium *et al.*, 2012) and The Cancer Genome Atlas (Collins, 2007) provide extremely useful SV sets for healthy and diseased genomes. In these datasets, it has been shown that the concordance of identified variants among different methods is generally modest (Tattini *et al.*, 2015). The most reliable strategy to identify SVs is to use multiple bioinformatics tools separately to detect the SVs. The SVs identified by each method are then merged. This method is effective in removing false positives at the expense of decreased sensitivity (Sudmant *et al.*, 2015).

The major hurdles for accurate variant calling can be divided into two categories. First, certain parts of human genome are hard to sequence experimentally. For example, DNA in heterochromatin regions cannot be easily fragmented while DNA library is being prepared (Shendure and Ji, 2008). A second hurdle is a bioinformatics problem, that is, a large fraction of the human genome is difficult to align to, because it contains repeated DNA sequences (de Koning *et al.*, 2011). This includes the transposable elements (such as Alu's), and segmental duplications of large chunks of human genome (Bailey and Eichler, 2006). The short reads that are sequenced from these regions cannot be uniquely mapped. Therefore, the variants in these regions are very hard, if not impossible, to detect. There are already bioinformatics methods developed to probabilistically assign reads in repeat regions. Even though these mitigate the effects of low mappability to a certain degree, short-read mapping to repeat regions remains an ongoing challenge.

The most promising (and logical) direction for the identification of variants in hard-to-map regions are long-read technologies, which include PacBio (Rhoads and Au, 2015), 10X (Zheng *et al.*, 2016), Illumina's Molecule (McCoy *et al.*, 2014), and Oxford Nanopore (Feng *et al.*, 2015). However, these long-read technologies often have different strengths and weaknesses. For example, PacBio generates very long reads, but with high error rates, while the 10X technology creates linked reads that have very low error rates, but are not exactly contiguous. There have been some bioinformatics tools that calibrate errors and call variants using data from long-read technologies (English *et al.*, 2014). Integrative bioinformatics methods are also in development, which utilize multiple long-read technologies in concert, to identify highly complex SVs and variants in the repeat regions and highly polymorphic regions, such as HLA locus (Nelson *et al.*, 2015). In addition, graph-based bioinformatics tools that use de-bruijn graphs have been used successfully in whole genome assembly and transcriptome assembly of long-read sequencing data (Lin *et al.*, 2016; Gordon *et al.*, 2016). New bioinformatics methods are utilized in cancer genomics to computationally de-convolve complex structural variation patterns in unstable cancer genomes (Zheng *et al.*, 2016) (please refer to the Section 'Detection of somatic variants in cancer genomes' for more discussion). Hence, long-read technologies, while still yielding notable issues, are nonetheless very powerful, especially when they are used in conjunction with traditional NGS (Mostovoy *et al.*, 2016).

Genotype Imputation

Genotype imputation is the process of predicting the genotypes of genetic variants that were not directly interrogated experimentally. It was conceptualized from the observation that some genomic variation is frequently observed to be associated with each other in the human population, i.e., they are in linkage disequilibrium (LD), and that these highly correlated variants can be

Fig. 1 Overview of a bioinformatic analysis of DNA sequencing reads in variant detection. First, the sequenced reads (wavy lines) are mapped to the genome (thick black line with arrowheads at termini) using read mapping tools. After mapping, the mapped reads (straight lines) at each location is counted to generate the read depth signal (blue line above the reads). A genomic deletion can be estimated when a drop in the read depth signal can be observed. Reads can be single-end (straight lines), or paired-end (reads connected by dashed lines with corners). When mapped to genes, reads can 'split' (reads connected by straight dashed lines), due to exon-intron junctions (exons are denoted by thick red lines on genome). Here, we focus on a specific genomic region (blue inset) to illustrate an example of read alignment and detection of an SNV (shaded yellow) and indel (shaded orange). For the SNV, a nucleotide change from 'G' to 'A' is supported by 2 reads, while an 'A' nucleotide deletion is supported by 3 reads. Some of the bioinformatics tools that use paired-end reads, split reads, and read depth are also shown (in grey below the blue inset).

inherited in haplotype blocks (Wall and Pritchard, 2003). The accuracy of imputation is contingent on both knowing the ‘phase’ (i.e., haplotypes) of the genetic markers, and the availability of accurate reference panels of LD patterns. Hence, there are two essential parts to *in silico* imputation: (1) the reference panel, and (2) the computational algorithm to estimate (or impute) the missing genotypes probabilistically, based on the haplotype information and LD patterns in the reference panel (Fig. 2).

Existing imputation reference panels are available, and already computationally constructed from large genotyping and sequencing studies (Fig. 2). The initial development of reference panels was first driven by the HapMap project for common variants (International HapMap Consortium *et al.*, 2007; The International HapMap 3 Consortium, 2010). Thus, imputation was skewed towards better estimation of genotypes from common variants. Further improvements in more recent years, particularly for the imputation of rare variants, came with the introduction of NGS and the 1000 Genomes Project (1000 Genomes Project Consortium *et al.*, 2012, 2015). Because imputation derives their genotype estimation from population allele frequencies, reference panels are typically built from larger consortia efforts with denser marker distribution and bigger and more diverse sample populations. They are constructed so that the allele frequencies of the genetic markers and LD patterns are better represented in accordance with ethnicities (Marchini and Howie, 2010). Reference panels can also be constructed by merging one’s own dataset with a reference panel, especially if the sample of interest is of an admixed origin or ethnic populations not found in the existing panels. Previous studies have already employed these existing and merged reference panels to successfully obtain rare variant imputation (Li *et al.*, 2011; Chen *et al.*, 2013). There are many bioinformatics tools and methodologies now that adopt several strategies with merging reference panels. For example, there has been early work where the merged panels are modeled jointly (Ewing *et al.*, 2012), or by first treating the panels as references for each other, and then imputing one’s data against the resultant panel (Howie *et al.*, 2009). There have also been strategies that used an ethnically diverse imputation panel, instead of a population-specific one, especially in situations where the dataset of interest is from an admixed population, or if the population of interest has a higher number of rare variants (Howie *et al.*, 2011).

There are many imputation tools currently available for use by the scientific community. They typically involve the following steps: phasing, which estimates the phase in the dataset of interest *in silico*, and then execute the genotype estimation process. There are many software for phasing, including MaCH (Li *et al.*, 2010), and SHAPEIT2 (Delaneau *et al.*, 2013). After phasing, the actual genotype imputation can be performed by several software, such as Minimac2 (Fuchsberger *et al.*, 2015), BEAGLE (Browning and Browning, 2011), and IMPUTE2 (Howie *et al.*, 2011). The performance and accuracy of these tools have been benchmarked and compared extensively in many publications over the years (Marchini and Howie, 2008; Roshyara *et al.*, 2016). Currently, there are also tools that use the biology of a specific genomic region to implement imputation, such as those that imputes genotypes in the complicated region of the major histocompatibility complex (MHC) (Karnes *et al.*, 2017).

Fig. 2 General process of genotype imputation of rare variants. The process of imputation typically starts with a sample dataset that is usually unphased and contain missing genotypes (denoted by ‘?’). If the starting dataset is genotyped from a microarray, one can additionally sequence part of the dataset to merge with a selected reference panel, or choose from an existing reference panel, e.g., 1000 Genomes Project or HapMap Project. Concurrently, *in silico* phasing can be performed to estimate the haplotypes for each individual in the sample dataset using tools such as MaCH and SHAPEIT2. Finally, imputation software such as Minimac2, BEAGLE and IMPUTE2 can perform imputation to approximate the missing genotypes probabilistically, by comparing the user haplotypes to the reference haplotypes.

Detection of Somatic Variants in Cancer Genomes

So far, we have discussed mostly about the detection of rare germline variants. There is an additional set of non-germline mutations, i.e., somatic variants, which are heavily studied and researched particularly in cancer genomes. Cancer genomes typically harbor many types of somatic variants that run the gamut. Whole genome or exome sequencing are used to detect SNVs, CNVs, indels and SVs, whereas RNA-sequencing is ideal for detecting fusion transcript events.

Somatic variants can be detected in cancer, by comparing the genomic alterations in tumor samples with their matched normal samples. Somatic variant calling is a very challenging task, because of the complex nature of cancers. Tumor heterogeneity, normal cell contamination, sequencing and alignment errors might all limit the ability to detect somatic variants, especially since somatic variants can be present at very low allelic levels. Therefore, sensitivity in somatic variant calling is very important in cancer. There are various popular bioinformatics methods for calling somatic SNVs and indels in cancer. Both MuTect (Cibulskis *et al.*, 2013) and Strelka (Saunders *et al.*, 2012) use a Bayesian approach to detect somatic variants. MuTect is especially designed to detect variants with a very low allele fraction. SomaticSniper (Larson *et al.*, 2012) uses a Bayesian framework to combine the genotype likelihood of tumor samples and normal samples. VarScan2 (Koboldt *et al.*, 2009) has a heuristic approach based on thresholds for read depth, base quality, variant allele frequency and statistical significance. There are also different computational methods for identifying CNVs in cancer genomes. Some of them consider other factors in their detection algorithms, such as normal cell contamination, ploidy and clonality of the tumor cells. Some of the most popular CNV calling methods include ExomeCNV (Sathirapongsasuti *et al.*, 2011), CoNIFER (Krumm *et al.*, 2012), VarScan2 (Koboldt *et al.*, 2009) and CONTRA (Li *et al.*, 2012). For SV detection in cancer, BreakDancer (Chen *et al.*, 2009) and Delly (Rausch *et al.*, 2012), are widely used.

Another important computational challenge in cancer is distinguishing driver variants from passenger variants. Driver mutations provide growth advantage to a tumor cell, thus promoting cancer development. MUSIC (Dees *et al.*, 2012), MutSig (Lawrence *et al.*, 2013), CHASM (Carter *et al.*, 2009), SIFT (Ng and Henikoff, 2003), PolyPhen (Adzhubei *et al.*, 2013) and other tools aim to predict *in silico* whether a somatic mutation is a driver or passenger, and prioritize candidate variants for downstream experiments.

Annotation of Rare Variation

With large-scale variant detection from sequencing and array technologies, a looming challenge is the rapid and efficient functional annotation of these variants in a high throughput fashion. One of the goals of *in silico* functional annotation is to be able to rank and prioritize variants for downstream experimental validation. The functional impact of rare variants can be estimated computationally in several ways, including comparative sequence analysis, and guilt-by-association. A secondary objective of the annotation process is to assess possible clinical impact of the variants, particularly in the context of diseases. These are typically tested in rare variant association studies (RVAS).

Impact Estimation for Rare Variants

We can estimate the impact of rare variants bioinformatically in different genomic contexts, and approaches. Often, the functional consequences of variants can be assessed in the context of the functional elements that it resides, in a guilt-by-association fashion. This requires prior knowledge of functional genomic elements that are provided by bioinformatics databases such as RefSeq (O'Leary *et al.*, 2016), Ensembl (O'Leary *et al.*, 2016), GENCODE (Harrow *et al.*, 2012a,b), and ENCODE (Dunham *et al.*, 2012). For example, Annovar (Wang *et al.*, 2010) and Ensembl's Variant Effect Predictor (VEP) (McLaren *et al.*, 2016) map rare variants of interest onto basic genomic features. Given a list of rare variants with genomic locations on the human reference genome, VEP can assess the potential impact of the variants, depending on whether they reside in an exon, intron, splice site or untranslated region. If the rare variant is found in a coding region, VEP can output whether the variant will cause a synonymous or non-synonymous change in the protein sequence. In non-coding regions, variants can be associated with key elements such as enhancers, DNA-binding motifs, and promoters.

By comparing multiple sequences across species or within species, more quantitative tools were developed to examine the likelihood of a particular variant to be functionally impactful, based on the various biological properties and genomic contexts. For example, the GERP score measures the divergence or sequence conservation of every base in the human genome, based on sequence comparison across multiple primate genomes (Cooper *et al.*, 2005; Davydov *et al.*, 2010). SIFT uses the BLOSUM matrix, which is derived from comparing inter-species homologous sequences, to estimate the likelihood of non-synonymous variants being deleterious (Ng and Henikoff, 2001). PolyPhen2 (Adzhubei *et al.*, 2013) additionally uses information from the three-dimensional structure of a protein to further examine the impact of a coding variant. Other computational tools such as FATHMM (Shihab *et al.*, 2013), ENTPRISE (Zhou *et al.*, 2016), and MutationTaster (Schwarz *et al.*, 2014) are also more recent additions. Funseq2 (Fu *et al.*, 2014) provides a score for a non-coding variant based on the integration of multiple layers of information, such as the position of a variant in regulatory networks, and the disruptive effect of the variant on DNA-binding motifs. Combined Annotation Dependent Depletion (CADD) algorithm (Kircher *et al.*, 2014) also outputs a score based on a support vector machine classifier that integrates multiple annotations into its prediction. A non-exhaustive list of currently available bioinformatics tools for functional impact estimation is available in Table 1. There is also a recent strategy of aggregating and computing the enrichment of rare allele-specific variants across multiple individual genomes, in order to identify regions that exhibit allele-specific behavior (Chen *et al.*, 2016).

Table 1 Table of bioinformatics tools that can annotate and prioritize rare variants. This table provides a list of bioinformatics tools that can estimate the functional impact of variants in three broad categories, namely tools that can annotate variants in the coding and noncoding regions, and tools that gives a score for each nucleotide in the genome, allowing quantification and prioritization of variants

<i>Software tool</i>	<i>Year first introduced</i>	<i>PubMed ID and citation</i>
<i>Coding-variant-based</i>

RVAS Studies: Predicting Functions of Rare Variants

The association studies are very useful for understanding the functional impact of variants in the context of traits and diseases. For example, GWASes give clues about the phenotypic effects of variants. In these studies, there is a sample with the disease or trait that is studied, termed the ‘case’ sample. There is also the ‘control’ sample, which includes individuals who do not have the manifestation of the disease or trait. The bioinformatics tools for GWAS look for genetic variants that are enriched in the case sample compared to the control sample. The enrichment of the variants indicate that the trait or disease associates with the variant (Bush and Moore, 2012). As mentioned, GWASes have identified thousands of loci that correlate with diverse set of traits and diseases, and can be found in the GWAS catalog (MacArthur *et al.*, 2017).

The GWASes generally address common variants that have small phenotypic effects (Fig. 3). These variants support the common variant common disease hypothesis (Pritchard and Cox, 2002), where many common variants with small effects culminate to a disease phenotype. However, based on heritability estimates in twin studies, the variants identified so far have been unable to account for all genetic contributions. Hence, for a while, researchers have thought that this ‘missing heritability’ can be explained at least in part by the effects of rare variants. This forms the basis of the rare-variant-common-disease hypothesis, which attributes rare variants to diseases (Cirulli and Goldstein, 2010).

In order to identify the effects of rare variants in traits and diseases, it is necessary to consider allelic heterogeneity, where different rare variants can affect a gene and give rise to the same phenotypic presentation. Moreover, there may be multiple causal genes. A bioinformatics method similar to GWAS can be deployed on rare variants to associate them with diseases and traits. These are termed generally as rare variant association studies (RVAS). In RVAS, it is necessary to use very large case and control sample sizes in order to obtain enough statistical power to detect the enrichment of rare variant alleles in the case sample (Lin, 2016). This may generally turn out to be impractical, especially if the prevalence of the rare allele is infinitesimally small. One approach is to group rare variants into biological elements, such as genes or signaling pathways. After grouping, a statistical test is performed to evaluate whether the element is under higher “burden” in the case sample compared to the control sample. This way, the association is computed for a region or element of multiple related rare variants, rather than a single variant. Because the frequency that an element is affected by the rare variants is increased, such burdening also increases the power of detection (Fig. 3). Most notably, RVAS studies have been useful in psychiatric diseases such as Alzheimer’s and Schizophrenia (Cruchaga *et al.*, 2014; Yang *et al.*, 2017; Singh *et al.*, 2017). SKAT (Wu *et al.*, 2011) is one of the most popular bioinformatics tools for performing various types of RVAS.

Fig. 3 Illustration of a burden test in a hypothetical RVAS study. This is a toy example showing the variants on a gene for eight individuals, four of whom are cases (with the trait or disease in question) and four are control samples. There are five mutations (red stars) in total that affect the gene X. The table summarizes the frequency of the variants in the case and control samples. Each mutation has a frequency of 25%, hence the individual mutations in the case sample do not show significant enrichment because each mutation is seen only once. However, when the mutations are counted on the gene as a whole, the case sample shows 4 times higher ‘burden’ compared to the control sample.

The accuracy of burden tests depends heavily on the precision and amount of element annotations. The annotations of protein coding genes on human genome can be assumed to be virtually complete (Harrow *et al.*, 2012a,b). It is, however, important to note that in the majority of GWAS and RVAS, variants are in non-coding regions of the genome (Zhang and Lupski, 2015). This implies that non-coding elements, like long non-coding RNAs and enhancers, must be studied in greater depth with respect to their functional roles. Moreover, the annotation of non-coding elements in the human genome is far from complete. Projects such as ENCODE (Bernstein *et al.*, 2012) and Roadmap Epigenome (Romanoski *et al.*, 2015) have been leading the way in the annotation of non-coding elements using functional genomics assays coupled with the corresponding bioinformatics pipelines, notably in ChIP-Seq (Harmanci *et al.*, 2014; Rozowsky *et al.*, 2009) and RNA-seq (Pepke *et al.*, 2009). Also, recent studies point to the importance of the three dimensional conformation of chromatin in genetic regulation (Belaghzal *et al.*, 2017). Taken altogether, understanding various non-coding elements can potentially enable a better delineation of the effects of rare variants when used in the RVAS studies.

One way to increase the power of RVAS studies is retrospectively combining results of previous RVAS studies. This bioinformatics analysis is referred to as meta-analysis of association studies (Begum *et al.*, 2012). Meta-analysis is very useful, because they make use of earlier association studies to increase the power of detection by increasing sample size. These methods combine the test statistics and p-values of individual studies to perform statistical test on the enrichment of rare variants in the pooled sample set. However, a major challenge is the computational adjustment for hidden covariates, such that the identified associations are based solely on genetic factors. Population stratification (Cardon and Palmer, 2003) and familial relationships (Manichaikul *et al.*, 2010) in the data are two major confounding factors that need to be adjusted for in association studies (Vilhjálmsdóttir and Nordborg, 2013).

Future Directions

As more research is being performed for rare variation, an important future direction is the development of novel and more effective statistical methods that are suitable for new sequencing technologies. This will be especially imperative for the technologies that generate long reads, which will enable genomics regions that were originally difficult to be sequenced by short reads to be made accessible. Using long-reads technologies, we will also be able to identify more accurately rare SVs, which will add more to our understanding of how these large variants affect diseases.

These developments will also bring new challenges. The large-scale sequencing efforts will generate a large number of variants, whose effects cannot be fully and quickly understood with the current knowledge and technologies. The new high throughput functional assays (Shalem *et al.*, 2015) have great potential in generating new data resources that can be combined with computational methods to better understand the effects of variants. These studies will also clarify how we should approach the classifications of rare and common variants with respect to their utility in public health and epidemiology (Visscher *et al.*, 2012). In addition to better uncovering their effects, sharing the data associated with variants of unknown significance (VUS) with patients will also create ethical challenges. We need to create standards and privacy-preserving frameworks for sharing these data. Understanding rare VUS will be best enabled using experimental protocols that follow up on

RVAS studies, by performing animal or cell culture experiments. These functional experiments are very important to functionally validate the identified GWAS and RVAS variants. Finally, the ethical considerations around sharing genomic data is still in its infancy in terms of implementation. Although there is a general consensus that genomic data may have adverse effects regarding the genomic privacy of the individual and his/her relatives, it is still an area of open debate as to how the balance between open data sharing incentives (Joly *et al.*, 2016) and privacy requirements can be maintained. In particular, the rare variants are one of the key aspects in genomic privacy, because they are private to a small group of individuals, so they can be sensitive enough for the identification of specific individuals (Homer *et al.*, 2008; Harmanci and Gerstein, 2016; Schadt *et al.*, 2012). New bioinformatic approaches will be necessary to share data related to rare variants in a privacy-preserving manner.

Closing Remarks

Our understanding of how rare variants impact human biology has come very far but is also still limited in many regards. In this article, we have reviewed some of the applications of bioinformatics in building computational approaches for detection and annotation of rare variants. We believe that increasing sample sizes in cohort studies, improving sequencing technologies, and new functional experiments will bring many exciting developments in the near future. Only through continued development and improvement of both experimental and computational methodologies, can we break new grounds.

Introduction

The recent advances in bioinformatics technologies produce a vast amount of genetic data. Since gene or protein variants are random and most variations have no harmful consequences, recognition of genetic deviations is usually an essential (Zhou *et al.*, 2016). Variations in the protein have influence not only in the protein structure but also its stability and function. nsSNVs and mutations can affect protein function in an abundant way. Besides, early detection of nsSNVs and mutations can be helpful in diagnosing the illness at a first stage, prognosis, prevention, and treatment of illness (Kulshreshtha *et al.*, 2016).

Bioinformatics analyses are necessary to predict contributing Amino Acid Substitutions (AAS) to human diseases for each genome (Kulshreshtha *et al.*, 2016). Expecting the functional effect of AAS caused by nsSNVs is becoming increasingly significant as more and more novel variants are being discovered to discriminate disease-associated mutations with non-disease mutations (Kulshreshtha *et al.*, 2016). One of the main challenges in the human genome is – to recognize functional effects of Single-nucleotide Variants (SNVs). Although some of the Variants found in genes assessed in the laboratory, many others have not evaluated for their possible damaging effects on protein structure and function (Hepp *et al.*, 2015).

Several existing methods in this field established over the years for expecting the impact of SNVs on human health (Kulshreshtha *et al.*, 2016). Nevertheless, they still have a high false prediction rate, which is overcome by computational approaches depend on combined features (Capriotti and Fariselli, 2017). Recently, these computational tools that are available on the website as web servers work on algorithms (a set of rules) can satisfy better predictions of the effect of SNVs if used combined from rather than alone (Kulshreshtha *et al.*, 2016).

In this study, we present web servers that can use in predicting SNVs or mutated protein stability that causes diseases. Computational web servers based on machine learning techniques (MLTs) Support Vector Machine (SVM), Random Forest (RF), Hidden Markov Models (HMM) and Artificial Neural Network (ANN) and so on. The servers can categorize according to variant information into protein structure, evolutionary conservation, sequence parameters and Combined features (Kulshreshtha *et al.*, 2016; Dong *et al.*, 2015). Consensus tools (integration of various instruments) with specific to protein features may do better than others with unfocused component scores (Dong *et al.*, 2015). By detecting diseases causing mutations, servers help to detect and understand genotype-phenotype associations, predict disease, and choose suitable treatments for patients.

Computational Approaches

A significant challenge is how to assess the disease relevance of genomic variations on a large scale. Single Nucleotide Variants (SNVs) are the most plentiful type of mutations in the human genome (Wang and Wei, 2016). The ability of computational tools to produce accurate and meaningful predictions at the protein level is not yet sufficient (Gallion *et al.*, 2017). In the last years, many methods (Web servers) have been established to predict the effect of nsSNVs which considered as unsolved problems earlier. Among the most popular servers, both SIFT and PolyPhen were developed and updated in several studies (Ng, 2003; Xi *et al.*, 2004; Li *et al.*, 2009; Adzhubei *et al.*, 2010; 2013; Sim *et al.*, 2012; Gallion *et al.*, 2017). Computational tools based on the MLT (SVM, RF, ANN, HMM and so on). It divided into several Techniques related to variants information, sequence homology, protein structure, combined features (structure and sequence) and consensus tool (scores of individual devices) as indicated in (Fig. 1).

Sequence-Based Approaches

Nowadays, a huge amount of data generated from various genome sequencing projects which are utilized for making libraries or databases and further, applied for comparison of the query sequence to the target sequence (Kulshreshtha *et al.*, 2016). *PhD-SNPg* was developed and compared with CADD and FATHMM by Capriotti and Fariselli (2017). It is a binary approach built on a Gradient Boosting algorithm. It can expect the effect of single and multiple SNVs from an input file included four elements, which indicate the chromosome, the position, reference and alternative alleles. Its output is a probability score between 0 and 1. When the score is > 0.5, the SNVs predicted as Pathogenic otherwise Benign. *PhD-SNPg* web server is a user-friendly interface to expect the influence of SNVs in coding and non-coding regions (Capriotti and Fariselli, 2017).

A web-based tool *Cancer-Specific high-throughput Annotation of Somatic Mutations (CHASM)* is a computational tool to recognize and prioritize those missense mutations best likely to produce functional changes that enhance tumor cell creation. The CHASM

Fig. 1 Overall framework of the categories of computational approaches.

method built on a Random Forest classifier (RF). The method has high sensitivity and specificity when discriminating between known driver missense mutations and randomly created missense mutations (area under ROC curve > 0.91). It outperforms other expectation methods in discriminating known oncogenic mutations in TP53 (Carter *et al.*, 2009).

The most straight forward tool is *Homotopy optimization method (HOPE)* where any user of the online web server can submit a sequence and mutation. It can also collect information about the protein from various sources (3D protein structure, UniProt Database, and DAS servers). It is used for the prediction of standard phenotypic effects caused by single amino acid change. It discriminates between neutral and deleterious mutations. Further, it builds a model of mutated protein if the amount of identity between the query sequence and Protein Data Bank (PDB) file exceeds the threshold value (Kulshreshtha *et al.*, 2016).

Another sequence-based tool, *The Sorting Intolerant from Tolerant (SIFT)* uses a sequence homology based on the Numerous Sequence Alignment (MSA) conservation approach to classifying the nsSNVs as tolerated or damaged to the protein. The SIFT score is the normalized possibility that the amino acid change is tolerated. The score ranges from 0 to 1 with a cutoff score of 0.05. Amino acid substitutions with (cutoff < 0.05) are predicted to be deleterious, and those with (cutoff ≥ 0.05) are expected to be tolerated (Hepp *et al.*, 2015).

Protein Variation Effect Analyzer (PROVEAN) is another sequence based tool for the expectation of the damaging effect of variations in protein sequences. The prediction is based on the modification, caused by a nsSNP, in the similarity of the sequence of related protein sequences in an MSA. PROVEAN uses a delta alignment score built on the reference and variant types of the protein sequence concerning the alignment of homologous sequences. A score equal or below the threshold of -2.5 determines the classification as a deleterious nsSNP (Hepp *et al.*, 2015).

Another tool, *Protein Analysis Through Evolutionary Relationships (PANTHER)* evaluates the likelihood that a particular nsSNP will cause a functional alteration of the protein. It calculates the replacement Position-Specific Evolutionary Conservation (sub-PSEC) score built on a Hidden Markov Model (HMM) alignment of evolutionarily related proteins. Substitution with positive values (subPSEC > 0) is shown as functionally neutral; whereas negative values of (subPSEC < 0) expect deleterious substitutions. A subPSEC score (cutoff of -3) parallels to a 50% probability that a nsSNP is deleterious to the protein, with a possibility of causing a deleterious impact on the protein function (P deleterious) of 0.5 (Mi *et al.*, 2016).

Also, *Functional Analysis through Hidden Markov Models (FATHMM)* tool, software for the forecast of the functional impacts of protein missense variations, was described by Shihab *et al.* (2012). FATHMM Software and server achieved performance accuracies that outperformed traditional forecast strategies (SIFT, PolyPhen, and PANTHER) on two distinct benchmarks. Furthermore, in one benchmark, they achieved performance accuracies that outperform current state-of-the-art forecast strategies (SNPs & GO and MutPred). FATHMM can be professionally applied to large-scale human and nonhuman genome sequencing projects with the other benefit of phenotypic outcome associations. The VariBench database is available at see "Relevant Websites section" and the SwissVar at see "Relevant Websites section" (Shihab *et al.*, 2013).

The Mutation Assessor tool also calculates stability score that predicts the effect of the mutation on protein. It relies on the evolutionary conservation approach and uses MSA to generate a conservation score, which classifies the mutation into three categories; neutral, low, high or medium. All these mutations affect the functionality of protein and their stability. This tool also used for SNPs associated with diseases such as cancer. It has its database for the prediction of diseases; however, it can retrieve data from other databases such as COSMIC and UniProt (Kulshreshtha *et al.*, 2016).

SNPdryad is a novel computational technique that can forecast the pernicious influence of amino acid replacements happened in human proteins. SNP dryad consistently outperforms other leading algorithms in accurately predicting deleterious nsSNVs. It uses different conservation scoring and uses RF as a classifier. The SNP dryad's input is a non-synonymous human SNP and the sequence of the human protein; the production is the predicted deleterious score for the input nsSNP. With high score value, predicted nsSNP be more deleterious. SNP dryad on the complete human proteome produces a forecast scores for all the possible amino acid substitutions (Wong and Zhang, 2014).

Structure-Based Approaches

These tools predict the stability changes by detecting structural properties as secondary structure. *Site-Directed Mutate (SDM)* web server was generated by Worth *et al.* (2011). The SDM server provides users with a fast and perfect evaluating the impact that a mutation will have on protein structure and stability. It gives a 3D view of the wild and mutant- sort. It is a worthy tool for recognizing possible illness associations and used for forecasting deleterious nsSNVs at the genome scale. To run SDM, clients must upload a wild-type structure and the position and amino acid type of the mutation. The returned results contain information about the local structural environment of the wild and mutant-sort, a stability score and illness associated forecast (Worth *et al.*, 2011).

The pathogenicity Prediction through Logistic Model tree (APOGEE) server was developed in 2017 by Castellana *et al.* APOGEE is a Machine Learning technique that outperforms all current prediction techniques in assessing the harmfulness of non-Synonymous genome variations. It is based on the classification model of the Logistic Model Tree (LMT), which syndicates the logistic regression models with tree introduction resulting in a single tree (Castellana *et al.*, 2017). Structure-based tools cannot use if the protein cannot be crystallized; this limitation can resolve by using sequence-based prediction tools (Kulshreshtha *et al.*, 2016).

Combined Features Based Tools

Several preceding studies presented and assessed novel computational model that predict the impact of amino acid allelic variants on protein structure and function. Structural based approaches can utilize only when the structure is known. Otherwise, sequence-

based approaches suggested. However, predicted the accuracy of sequence-based approaches is lower than the structure-based approaches. None of them is confirmed to be accurate and provide complete mutant protein analysis. The prediction accuracy can increase by using the right combination of features. Therefore, combined and consensus approaches are developed with increased accuracy and efficiency and for use in all situations (Kulshreshtha *et al.*, 2016).

PON-PS is the first generic tool for classification of amino acid substitutions associated with benign, severe, and less severe phenotypes. It combines the PON-P2 pathogenicity predictor and an ML model that classifies variants into three categories showed an accuracy of 61% in the test dataset which is higher than for existing tolerance prediction methods. PON-PS also helps to detect and understand genotype-phenotype correlations (Niroula and Vihinen, 2017).

PON-P2 is a new computational technique for sorting of amino acid variations in human proteins. It is a Machine Learning based classifier that clusters the variants into pathogenic, neutral and unknown classes, by Random Forest likelihood score. It is trained using pathogenic and neutral variants obtained from the VariBench dataset. It uses information about evolutionary conservation of sequences, biochemical properties of amino acids, physical and if available, functional annotations of variation sites. It consistently showed more significant performance in comparison to existing tools. In 10-fold cross-validation test, its accuracy and MCC are 0.86 and 0.71, respectively. PON-P2 is a powerful tool for showing and ranking deleterious variants (Niroula *et al.*, 2015).

ENTPRISE webserver can predict disease-associated/cancer driver variations. It also performs excellently and better than some of the established methods such as Mutation Assessor and PolyPhen-2 for cancer driver prediction on the COSMIC data. The combination of the parameters (amino acid type, sequence entropy and contacting the residue composition) makes ENTPRISE do well in all over tests (Zhou *et al.*, 2016).

Integrated Functional inference of SNVs in human (iFish) is also a new online web server, which had flexible functionalities and user-friendly interfaces that permit users to analyze large sets of nsSNVs rapidly. iFish could predict the pathogenicity of human nsSNVs with increased accuracy. It outperformed other existing techniques on independent benchmarking datasets. It supports the collection of genetic evidence into the expectation of pathogenicity using a Bayesian model. Inputs specified by the chromosome, position, reference allele and an alternative allele of each nsSNV. It also enables registered users to create their gene-specific classifiers using their variations, which is not available with other existing tools. (iFish) accomplished high accuracies and outperformed other existing tools (Wang and Wei, 2016).

Screening for Non-Acceptable Polymorphisms (SNAP) is also a neural network-based method for the expectation of the functional effects of nsSNVs. SNAP uses features for the residue conservation within sequence families as protein structure and annotations, when available. It receipts protein sequences and lists of mutants and delivers a score for each substitution, which can then convert into binary predictions of a neutral or non-neutral effect (Hepp *et al.*, 2015).

Polymorphism Phenotyping v2 (Polyphen-2) is a structure and sequence-based method that determines the structural and functional consequences of nsSNVs. The PolyPhen-2 that capable of analyzing vast volumes of data created by Next-generation sequencing projects calculates the probability that a Bayesian classifier damages a nsSNP. It is an automatic tool for the expectation of the probable effect of an amino acid exchange on the structure and function of a human protein (Adzhubei *et al.*, 2013).

Another combined based tool *SNPs & GO* is a method based on SVM to predict disease-related mutations from the protein sequence, which uses information derived from evolutionary information. Protein sequence and function as encoded in the Gene Ontology (GO) terms annotation to expect if a given mutation can be secret as disease-related or neutral (Hepp *et al.*, 2015). It was implemented and updated by Capriotti *et al.* (2012). Its input comprises the sequence and its structure (when available), a set of target variants and its functional Gene Ontology (GO) terms, while the output of the server delivers, for each protein variation, is the probabilities to be related to human diseases. It tested on a massive set of marked variations extracted from the SwissVar database. The results of the server are (79% and 83%) overall accuracy for the sequence-based and structure-based inputs, respectively (Capriotti *et al.*, 2013b).

Pseudo Amino Acid Composition (PaPI) is a new machine-learning tool to sort and score human coding variations by estimating the probability to damage their protein-related function. The combination of pseudo amino acid composition, evolutionary conservation, and homologous proteins based methods outperform various prediction techniques, and it is also able to score multiple variants such as deletions, insertions, and indels (Mi *et al.*, 2016). The Position-Specific Independent Count (PSIC) of the results of the server ranges from 0 to 1. The categorization of the nsSNVs results is probably damaging and possibly damaging (PSIC > 0.5) or Benign (PSIC < 0.5) (Hepp *et al.*, 2015).

Consensus Tools With Combined Features

Consensus tools based on the integration of various tools. It provides information that needs to design a novel protein with desired characteristic and stability (Kulshreshtha *et al.*, 2016). Some classifying tools have been improved their accuracy by integrating them with other tools. Where each tool built on the specific dataset, the combination of these individual tools in a consensus classifier is enough to improve the classification capacity. Many studies cooperate in this kind of classifications.

PON-P is a Meta classifier that combines the outputs from the five methods (SIFT, PhD-SNP, PolyPhen-2, SNAP and I-Mutant 3.0) to predict the possibility that a nsSNP will affect protein function and may so be disease-related. It utilizes RF for predicting whether variants affect functioning and lead to diseases. The (PON-P) classifies the nsSNVs as neutral, unclassified or pathogenic with a corresponding possibility of pathogenicity, and provides the data existing in the UniProt database for each entry (Hepp *et al.*, 2015).

Predict SNP1.0 is an SNP classifier technique that merges six forecast techniques (MAPP, PhD-SNP, PolyPhen-1, PolyPhen-2, SIFT, and SNAP) to gain a consensus expectation of the result of the amino acid substitution. The six prediction tools run by a dataset of non-redundant mutations. The individual confidence scores are transformed to percentages to allow comparison and

the individual predictions combined in the consensus prediction. Most of these tools based on machine learning methods, primarily designed to classify neutral and deleterious mutations by sequence and structural parameters. It provides a consensus prediction with improved accuracy and efficiency over individual integrated tools (Bendl *et al.*, 2014).

Combined Annotation Dependent Depletion (Condel) is also a consensus tool which developed by integrating SIFT, PolyPhen-2, and Mutation Assessor. It collects, assembles and presents the results obtained by these tools. Condel can use as a web server or standalone tool (run on the computer after downloading).

Recently, *Rare Exome Variant Ensemble Learner (REVEL)* developed by Ioannidis *et al.* (2016) is a standard technique for expecting the pathogenicity of missense variants by individual tools. MutPred, FATHMM, VEST, Poly-Phen, SIFT, PROVEAN, Mutation Assessor, Mutation Taster, LRT, GERP, SiPhy, phyloP, and past Cons. REVEL had the best global performance as compared to any individual tool and seven ensemble methods: Meta SVM, MetaLR, KGGSeq, Condel, CADD, DANN, and Eigen. It is a standard technique that outperforms existing tools for distinguishing pathogenic variants from rare neutral variants (Ioannidis *et al.*, 2016).

Meta-SNP presented by Capriotti *et al.* (2013a,b) as a new approach for the discovery of illness-associated ns-SNVs that integrates four existing strategies: PANTHER, PhD-SNP, SIFT, and SNAP find that the Meta-SNP algorithm realizes better performance than the best single predictor. The results showed that the combination of forecasts from various resources is a good plan for the selection of high-reliability forecasts Capriotti *et al.* (2013a).

Consensus Variant Effect Classification (COVEC) is a Meta classifier that mixes the expected results of four methods SIFT, PolyPhen2, SNPs & GO and Mutation Assessor. The COVEC method outperforms unique methods and highlights the advantage of merging results from multiple tools. The SVM-based consensus classifier combines the raw output scores generated from these tools. The SVM model performs the classification using either a linear kernel or a radial based function (RBF) (Frousios *et al.*, 2013).

Consensus tools enhance accuracy and efficiency of the unique tools and predict the results better than any other tool. These tools provide a platform for comparing the results achieved by different tools in a familiar place and hence, reduce the efforts required to study the data by using different tools individually (Kulshreshtha *et al.*, 2016).

Web Servers as a Tool for Predicting the Snvs

Computational approaches, online web server, are tools for expecting the impact of SNVs on protein stability and function. After selecting the suitable database and determining the parameters affecting function and stability of the mutant protein, predicting the influence of SNVs on protein function and stability can do with the help of different computational approaches and tools. These tools are built on machine learning methods to detect and use non- redundant features that required for forecasting the effects of amino acid substitutes on protein function and classifying mutations as damaging or neutral (Kulshreshtha *et al.*, 2016).

Recent studies have indicated that the altering human behaviors have a significant influence on genetic variation (Bermejo *et al.*, 2014). Here, we launch a comprehensive review on an individual and ensemble servers for mutation analysis. We collect the most common unique tools in (Table 1) and ensemble tools in (Table 2) with their Web site, MLT that based on, Input parameters, Deleterious Threshold & Outputs, and references. The performance of the most widely used tools in predicting nsSNVs in (Table 3) through ACC (accuracy), AUC (Area under the curve), and MCC (Math well Correlation Coefficient). In additional to, Accuracy of the best singular and consensus tools that recently developed displayed in (Fig. 2).

Conclusion

In the last decade, many tools have been progressed to expect the effect of SNPs and mutation on genomic location, and on translated protein (synonymous and non-synonymous SNPs) that was considered as unsolved problems earlier (Kulshreshtha *et al.*, 2016). Recently, consensus tools have established by incorporating many tools together, which provided single window results for comparison purposes (Kaminker *et al.*, 2007). It also noted that the best ensemble scores not require a massive number of component scores to improve performance significantly, but need integrated component scores that are specific to protein features to be a marked improvement in performance. For example, KGGSeq, which integrated five module scores (SIFT, PolyPhen-2, LRT, Mutation Taster and PhyloP), performed healthy than (CADD), which integrated more than 40 component scores (Dong *et al.*, 2015).

In this review, we have performed a comprehensive study of several popular and recent prediction techniques to discriminate the pathogenic nsSNVs. It provides the fundamental knowledge based on sequence, structure and evolutionary relationship. These tools provide more reliable and accurate prediction due to compelling and comparing data from various tools. We found that some of them updated for already existing servers, others are the novel servers, while others are ensemble servers (integrated individual). Several previous studies have provided comparisons between many servers to highlight the most accurate and efficient servers and to combine them in an ensemble (Meta) server that enhances the expecting performance.

Finally, after doing a comprehensive review on all these categories of computational approaches, most studies conclude that Meta predictions are better than an individual tool. Many advanced computational approaches have been established over the years, to forecast the function and stability of a mutated protein. These methodologies based on structure, sequence features and combined features (both structure and sequence features) provide an accurate valuation of the influence of amino acid exchange on function and stability protein. By comparing the results, we realized from the range of servers performance (Table 3) and (Fig. 2) that REVEL, CADD, COVEC, Meta-SNP, PAPI, and Condel are better tools than other ensemble tools and PON-P2, SNP dryad, CHASM, PROVEAN, PhD-SNP[®], and Mutation Assessor are better tools than other individual tools. The consensus techniques have the highest overall performance.

29	REVEL (Rare Exome Variant Ensemble Learner)	89	90–95.7	–
30	CADD (Combined Annotation Dependent Depletion)	76.20–87	77–92	0.53–74
31	DANN (Deep Artificial Neural Network)	66.1	70–95.6	–

**Fig. 2** Accuracy of the best individual and ensemble classifiers.

We concluded that consensus classifiers are better than single ones. We recommend using multiple prediction algorithms as well as more available genetic level information may help to enhance the predictive power. This review is a useful user guide for future studies based on web servers for prediction the impact of genetic variants in human diseases.

Genome Analysis – Identification of Genes Involved in Host-Pathogen Protein-Protein Interaction Networks

Fransiskus Xavierius Ivan, Jie Zheng, and Chee-Keong Kwoh, Nanyang Technological University, Singapore
Vincent TK Chow, National University of Singapore, Singapore

© 2019 Elsevier Inc. All rights reserved.

Introduction

Among various types of molecular networks, host-pathogen protein-protein interaction (HP-PPI) networks have been considered as one of the most important types (Stebbins, 2005; Korkin *et al.*, 2011; Zoraghi and Reiner, 2013) in the study of infectious diseases. Advances in understanding the nature of HP-PPIs could enlighten ourselves as to the principles of mechanisms for the infection mechanisms by pathogens. A few principles have been proposed, including the specificity and multiplicity of pathogen proteins in targeting the host proteins, and the preference of pathogen proteins in targeting the hubs of the host protein-protein interaction networks (Arnold *et al.*, 2012). Recently, the centrality of a pathogen protein in the host-pathogen interactome, but not pathogen interactome, is shown to correlate with the fitness of the pathogen during *in vivo* infection (Asensio *et al.*, 2017). Knowledge of such network wiring would pave the way for implementing network medicine which may provide novel strategies for determining therapeutic targets and altering a disease state to a normal state (Barabási *et al.*, 2011).

To uncover HP-PPI networks, several high-throughput experimental techniques have been available and reviewed by Nicod *et al.* (2017). Of particular interest is the yeast two-hybrid (Y2H), an *in vivo* technique which detects an interaction based on the reconstitution of a functional transcription factor. This method has been used to uncover interactions between human proteins and proteins from varying viruses, including hepatitis C virus (De Chasseay *et al.*, 2008; Dolan *et al.*, 2013), herpesvirus (Lee *et al.*, 2011), influenza virus (Shapira *et al.*, 2009) and various flaviviruses (Le Breton *et al.*, 2011; Khadka *et al.*, 2011; Mairiang *et al.*, 2013) and oncoviruses (Calderwood *et al.*, 2007; Gulbahce *et al.*, 2012; Muller *et al.*, 2012; Rozenblatt-Rosen *et al.*, 2012). To some extent, it has also been limitedly used to uncover interactions between human proteins and effectors of varying bacteria and parasites, including *Bacillus anthracis* (Dyer *et al.*, 2010), *Burkholderia mallei* (Memisević *et al.*, 2013), *Escherichia coli* (Blasche *et al.*, 2014), *Francisella tularensis* (Dyer *et al.*, 2010; Wallqvist *et al.*, 2015), *Mycobacterium tuberculosis* (Mehra *et al.*, 2013), *Yersinia pestis* (Dyer *et al.*, 2010; Yang *et al.*, 2011), and *Toxoplasma gondii* (Liu *et al.*, 2017). However, note that although Y2H technique can test the interaction between any pair of proteins, it may not capture the interactions between proteins that require posttranslational modification in their original organisms and proteins that are not localized in the nucleus.

In addition to Y2H, high-throughput proteomic approaches have also gained popularity for uncovering HP-PPIs in the recent years. Among them, mass spectrometry (MS) based methods are the most common ones. Unlike Y2H, MS methods can provide information related to posttranslational modifications and capture interactions in physiologically relevant conditions. Additionally, MS methods also allow quantification of proteome to compare changes of proteins complexes between biological conditions. Unfortunately, most MS methods are not highly sensitive and sometimes require high amounts of purified protein complexes that are hard to be obtained (Nicod *et al.*, 2017). One of the most promising MS methods is coupled with affinity purification (AP), and it has been mainly used to study HP-PPIs during virus infections. These include infections by hepatitis C virus (Germain *et al.*, 2014; Ramage *et al.*, 2015), herpesvirus (Davis *et al.*, 2015), HIV (Jäger *et al.*, 2011; Kane *et al.*, 2015), influenza virus (Watanabe *et al.*, 2014), and various flaviviruses (Colpitts *et al.*, 2011) and oncoviruses (Rozenblatt-Rosen *et al.*, 2012; White *et al.*, 2012a). Further highlights to the application of MS methods on resolving HP-PPIs can be found in Gerold *et al.* (2016). MS methods have also been limitedly used to study HP-PPIs during infections by bacteria and parasites, including *Salmonella* (Auweter *et al.*, 2011), *Chlamydia trachomatis* (Mirrashidi *et al.*, 2015) and *Plasmodium falciparum* (Swearingen *et al.*, 2016).

Another emerging approach to identifying genes involved in HP-PPI networks is the dual RNA-seq technique which simultaneously captures transcripts in both the host and pathogen organisms (Westermann *et al.*, 2017). The method has been applied to studying interactions between human/animal proteins and proteins from various pathogens, including *Chlamydia trachomatis* (Humphrys *et al.*, 2013), *Lawsonia intracellularis* (Vannucci *et al.*, 2013), *Escherichia coli* (Mavromatis *et al.*, 2015), *Mycobacterium bovis* (Rienksma *et al.*, 2015), *Haemophilus influenzae* (Baddal *et al.*, 2015), *Salmonella typhi* (Avraham *et al.*, 2015; Westermann *et al.*, 2016) and *Streptococcus pneumoniae* (Aprianto *et al.*, 2016). For revealing the HP-PPI networks, a correlation between host's and pathogen's gene expression profiles can be reliably used; however, it must be noted that both direct and indirect interactions may be detected by the correlation methods (Reid and Berriman, 2013).

Despite their promising performance, experimental high-throughput approaches are costly and labor-intensive. Moreover, as discussed above, the resultant datasets may have inherent noises, biases and limited coverage (see Xing *et al.*, 2016 for detailed discussions on technological issues and flaws of various experimental methods). Thus, in light of limited reliability and voluminous nature of HP-PPI data, predictive computational methods that integrate genome-wide data sources would be a great complement to the experimental techniques in exploring the full range of possible genes involved in HP-PPIs.

Here, we review the latest achievements in the integrated genome-wide computational prediction of HP-PPI networks. First, we describe a workflow for predicting HP-PPI networks and highlight two different principles for detecting interacting pairs of proteins. Secondly, we illustrate several case studies in the area of human infectious diseases and categorize them according to the

types of pathogens. We highlight several aspects that need to be considered when uncovering related HP-PPI networks. Finally, we discuss issues on the methods, highlight efforts that have been made to address them, and outline future developmental works in the area.

Workflow for Predicting Host-Pathogen Protein-Protein Interactions

From a survey of the literature and previous literature reviews (Arnold *et al.*, 2012; Zhou *et al.*, 2013a; Nourani *et al.*, 2015; Sen *et al.*, 2016), we have recognized that a workflow for predicting genes involved in HP-PPI networks can be divided into four stages: (1) retrieval of host-pathogen genomes and PPI data, (2) detecting potential HP-PPIs, (3) filtering predicted HP-PPIs, and (4) validating predicted HP-PPIs. These stages are explained in detail in the following subsections.

Retrieval of Host-Pathogen Genomes/Proteomes and Protein-Protein Interaction Data

To conduct an investigation on HP-PPI networks, we must first collect genomes or proteomes of host and pathogen of interest. If available, such data can be retrieved from free genome or proteome repositories in NCBI (NCBI Resource Coordinators, 2017), ENA (Toribio *et al.*, 2017), ENSEMBL (Kersey *et al.*, 2016), or UniProt (The UniProt Consortium, 2017), as well as specialized ones such as CryptoDB (Heiges *et al.*, 2006), ToxoDB (Gajria *et al.*, 2008), PlasmoDB (Aurrecochea *et al.*, 2009), TubercuList (Lew *et al.*, 2011), GeneDB (Logan-Klumpner *et al.*, 2012), EuPathDB (Aurrecochea *et al.*, 2017), HIV Sequence Databases (Kuiken *et al.*, 2003), and many others.

Next, we require protein-protein interaction (PPI) datasets that can be considered as the ground truth for predicting new HP-PPIs. A number of specialized or generalized databases have been available, and they mainly include intra-species protein-protein interaction data. Some databases that maintain HP-PPI datasets have also been developed, including PHISTO (Durmuş *et al.*, 2013), VirHostNet (Guirimand *et al.*, 2015), HPIDB (Ammari *et al.*, 2016) and PHI-base (Urban *et al.*, 2017). In addition to those databases, PDB (Rose *et al.*, 2017) is also a valuable resource for collecting interaction data along with their protein structures; while 3did database (Mosca *et al.*, 2014) a secondary database that provides information about 3D interacting domains extracted from PDB. The list of PPI databases that have been used for investigations and are still actively maintained is given in Table 1. One important note is that the databases may contain PPIs that are uncovered from literature by an automated text mining approach. A recent review of the development of text mining approaches for HP-PPI recovery from literatures is given by Durmuş *et al.* (2015).

Fig. 1 Two principles for detecting potential HP-PPI between host protein H and pathogen protein P. (A) Similarity-based detection: H and P interact if each of them is similar to a different component of a known interacting protein pair. The similarity can be either based on sequences, domains, motifs, or structures. (B) Learning-based detection: The interaction between H and P is decided by a learner that is constructed using an association rule learning or a supervised machine learning approach. Association rule learning relies only on feature dataset extracted from known protein-protein interactions (PPIs), while supervised machine learning must be trained using feature datasets from both interacting and noninteracting protein pairs.

Detecting Potential Host-Pathogen Protein-Protein Interactions

At this stage, potential protein-protein interactions are detected by using known intra-species PPI or HP-PPI datasets as the ground truth. In general, there are two classes of methods for detecting potential interactions: similarity-based and learning-based methods. In principles, similarity-based methods compare the sequences, domains, motifs, or structures of candidate interacting protein pairs with those of known interacting protein pairs; while learning-based methods generate features from candidate and known interacting protein pairs for training a classifier or constructing rules for predictions. Illustration of these principles is presented in Fig. 1. Although both similarity- and learning-based approaches can be combined, here we explain each method separately.

Similarity-based detection methods

Similarity-based detection methods rely on the assumption that “If protein A and protein B are known to interact, and we have A' and B' are respectively similar to A and B in terms of sequence, domain, motif, or 3D information structures, then we may conclude that A' and B' are potential to interact”. Sequence similarity indicates homology or evolutionary relationship between sequences, and thus the method is often referred to as a homology-based method. Predicted interactions by homology-based methods are called interologs. Several databases have been developed to store information on homologous sequences, which include OrthoMCL-DB (Fischer *et al.*, 2011), InParanoid (Sonnhammer and Östlund, 2015), NCBI HomoloGene (NCBI Resource Coordinators, 2017) and OrthoDB (Zdobnov *et al.*, 2017); and thus, inference on interologs could be eased with the presence of such databases. In the absence of homologous information, homology between a host or a pathogen protein with a known interacting protein can be assessed by using BLASTP (Altschul *et al.*, 1990). For capturing distant similarity, PSI-BLAST (Altschul *et al.*, 1997; Schäffer *et al.*, 2001) should be considered. Tools for quick ortholog (homolog due to speciation) assignments between two genomes from different species, which include free tools that are used to create OrthoDB, OrthoMCL-DB, and InParanoid, may also be employed.

Similarly, classification of domain or motif of protein sequences can be checked in domain or motif databases (especially Pfam database (Finn *et al.*, 2016)) and used for predicting protein-protein interactions. Domain or motif of new protein sequences (proteins that are not in the databases) can be classified using various domain or motif search tools, including TMHMM (Krogh *et al.*, 2001), ScanProsite (De Castro *et al.*, 2006), HMMER (Mistry *et al.*, 2013), InterProScan (Jones *et al.*, 2014), RPS-BLAST (Marchler-Bauer *et al.*, 2015) and ELM (Dinkel *et al.*, 2016). For 3D structure, similar protein structures in PDB can be obtained in Dali Database (Holm and Rosenström, 2010) or SCOP2 (Andreeva *et al.*, 2014), while similarity search for query protein structures against protein structures in PDB can be done using DaliLite (Holm *et al.*, 2008). DaliLite, or alternatively TM-align (Zhang and Skolnick, 2005) may also be used for comparing two protein structures in a local database; alternatively. If only protein sequences are available, 3D structures of the proteins can be first predicted before performing similarity search. The

prediction can be done by using software such as I-TASSER (Yang *et al.*, 2015) and MODELLER (Webb and Sali, 2016) and utilizing PDB's structural information as a template. Respectively, **Tables 2** and **3** summarize repositories and search tools that are available publicly.

Learning-based detection methods

Learning-based detection methods have been widely applied for predicting HP-PPIs. Supervised machine learning methods, such as logistic regression, multilayer perceptron, random forest and support vector machine, have been applied in the presence of positive and negative datasets (i.e., interacting and noninteracting protein pairs). Regardless of the methods they use, and whether it is a single-task or multi-task learning, or involves transfer learning or not, generation of features for labeled data is crucial to apply supervised learning-based methods. The features have been extracted from various resources, including features from interacting proteins (sequence, domain, and motif features), known HP-PPI data (HP-PPIs with experimental evidence), network topology (mainly from host interactome), Gene Ontology (GO) annotations, and other varying biological contexts. A summary of features that have been used for prediction is shown in **Table 4**. Among them, *k*-mer composition of host and pathogen proteins has been the most popular feature being used.

Nonetheless, some authors (Mukhopadhyay *et al.*, 2010, 2012, 2014; Mondal *et al.*, 2012; Ray *et al.*, 2012; Nouretdinov *et al.*, 2012) have argued that negative dataset or a list of noninteracting protein pairs cannot be defined precisely. In this case, they proposed the use of association rule learning, a data mining approach for discovering interesting relations between items in a large dataset. Highlights about their methods are presented in the case studies.

Filtering Predicted Host-Pathogen Protein-Protein Interactions

Detection methods usually come along with a threshold parameter that needs to be set in order to obtain potential interactions with significant evidence. For example, when using BLASTP for detecting homology or sequence similarity, we must determine a cut-off for E-value for reasonable results. The choice of the parameter is made to maximize the proportion of true interactions without getting a significant proportion of negative interactions. In addition to filters associated with detection methods,

	Structural features – A variety of features derived from the structural component of host-pathogen protein pairs	Halder <i>et al.</i> (2017)

biological-context-based and structural-based filters have also been widely applied, especially when similarity-based methods are used to detect potential HP-PPIs. Biological-context-based filters utilize information related to molecular characteristics, cellular localization and functions, tissue specificity, pathogenicity, and gene expressions. Structural-based filters can be as simple as homomeric information and as complex as a score that measures interaction strength between residues in the interface of interacting host and pathogen protein pairs.

Validating Predicted Host-Pathogen Protein-Protein Interactions

Several methods have been used to validate the results of predicted host-pathogen interactions. Among them, one of the common methods is literature validation, where predicted HP-PPIs are matched with reported interactions that have experimental evidence. Another popular method is the gene set enrichment or over-representation analyses. This is commonly done by computing the significance of the overlap between the set of predicted host genes involved in HP-PPI networks and the set of proteins belong to the same GO category using a hypergeometric distribution. Specifically, if N is the total number of genes associated with a host genome, M is the number of genes belongs to a specific GO category, n is the number of predicted host genes involved in HP-PPI networks, and x is the number of predicted genes in the GO category, then the significance of observing x or more predicted genes in the GO category is given by the following formula:

$$p - value = \sum_{j=x}^n \frac{\binom{M}{j} \binom{N-M}{n-j}}{\binom{N}{n}}$$

As an alternative to GO categories, other lists of genes may also be used for enrichment analyses. These include a list of genes appeared in the same pathway or obtained from expression profiling and RNAi screening.

Network analyses have also been used to assess the prediction results of interacting proteins. Common network topology measures such as degree, betweenness centrality, shortest path length, clustering and density coefficients, number of connected components, and scale-freeness of the networks have been calculated for intra-host or host-pathogen PPIs (see [Costa et al., 2007](#) for a survey of various network measurements). Some other interesting measures that have been proposed are the distribution of distances between host protein pairs interacting with a particular pathogen protein (and vice versa; [Dyer et al., 2007](#)) and pathway participation coefficient that measures the diversity of the pathways for host protein's binding partners ([Wuchty, 2011](#)).

Some other methods for validating predicted interactions use aspects of data that are not exploited for predictions or filtering. For examples, [Tyagi et al. \(2009\)](#) used the superposition of predicted complex and template PDB structure to evaluate prediction results detected by homology- and domain-based methods, while [Dyer et al. \(2007\)](#) computed distribution of Spearman's correlation between the expression profiles of the protein pairs to evaluate predictions based on domain-based method. Additionally, methods for assessing the statistical significance of predicted interactions by using randomized interactions have also been proposed by [Doolittle and Gomez \(2010\)](#) and [Itzhaki \(2011\)](#).

Case Studies on Predicting Human-Pathogen Protein-Protein Interactions

To illustrate the application of the workflow for predicting HP-PPIs, we highlight their uses in uncovering protein-protein interactions that underlie human infectious diseases caused by viruses, bacteria, and parasites. [Table 5](#) lists studies that have been carried for each category of the pathogen. Depending on the type of the pathogen, a unique strategy might be applied to predict HP-PPIs.

Uncovering Human-Virus Protein-Protein Interactions

Human-virus interactions have been investigated for varying viruses, including dengue virus, Ebola virus, HIV, herpes simplex virus, influenza virus and varying oncoviruses (adenovirus, Epstein-Barr virus, hepatitis C virus, human papillomavirus, human T-lymphotropic virus, and Kaposi's sarcoma-associated herpesvirus). Among them, HIV has been widely studied and our discussion will focus on it. Different detection methods have been applied to identify potential interactions between human proteins and HIV proteins, including domain-/motif-based similarity ([Evans et al., 2009](#); [Segura-Cabrera et al., 2013](#); [Becerra et al., 2017](#)), structural-based similarity ([Doolittle and Gomez, 2010](#); [Cui et al., 2016](#)), supervised machine learning ([Tastan et al., 2009](#); [Qi et al., 2010](#); [Dyer et al., 2011](#); [Nouretdinov et al., 2012](#); [Mei, 2013](#); [Abbasi and Minhas, 2016](#)), and rule mining ([Mukhopadhyay et al., 2010, 2012, 2014](#); [Mondal et al., 2012](#); [Ray et al., 2012](#)).

Of those methods, the domain-/motif-based similarity and rules mining have been uniquely carried out for HIV. [Evans et al. \(2009\)](#) and [Becerra et al. \(2017\)](#) proposed a method that is based on direct interactions between host-mimicked short eukaryotic linear motifs (ELMs or SLiMs) and cluster domains (CDs) that are present in HIV-1 and human proteins, respectively. Different types of filters for ELMs – including conservation level, rarity, and association with disordered regions – have also been assessed by [Becerra et al. \(2017\)](#), demonstrating that the majority of conserved ELMs are associated with disordered regions. On the other

^aAcronyms for learning-based methods – AMPKE: adapted multiple kernel preserving embedding; ARs: association rules; CP: conformal predictor; DT: decision tree; ELM: extreme learning machine; KNN: k-nearest neighbor; MLP: multi-layer perceptron; NB: naïve Bayes; RF: random forest; SCW: soft confidence-weighted; SDA: stacked denoising autoencoder; SGD: stochastic gradient descent; SVM: support vector machine.

hand, Segura-Cabrera *et al.* (2013) utilized motif information from 3did datasets, in combination with a filter based on surface accessibility of motif residues.

The second method extracts association rules from only known interactions using a biclustering for predicting new interactions between HIV and human proteins (Mukhopadhyay *et al.*, 2010, 2012, 2014; Mondal *et al.*, 2012; Ray *et al.*, 2012). For this, the known interactions are presented as a matrix with rows and columns represent the viral and human proteins, respectively. Each entry of the matrix indicates a type of interaction. For extracting association rules as done for market basket or transaction data analysis, we consider each row as a transaction and each column as an item. If we have $[HP_1 HP_2 \dots HP_k] \rightarrow [HP_{k+1} HP_{k+2} \dots HP_m]$ as a highly confident rule, where each HP_i represents a host protein, then we basically infer that HP_{k+1} , HP_{k+2} , ..., and HP_m interact with each of viral protein that interacts with each of HP_1 , HP_2 , ..., and HP_k .

Of particular interest from those studies is small overlaps between the sets of interactions predicted using different approaches, which is a standing issue in HP-PPI prediction (Mukhopadhyay *et al.*, 2012, 2014; Segura-Cabrera *et al.*, 2013). Despite such inconsistency, HP-PPI predictions that utilize homology-based detection method and structural information has helped to provide insights about structural principles governing the interactions between human and viral proteins (Franzosa and Xia, 2011). These include the characteristics of HP-PPI interfaces that mimic host's PPI interfaces, but they are governed by their own structural, functional and evolutionary principles.

Uncovering Human-Bacterial Protein-Protein Interactions

Various detection methods have been applied independently or in different combinations to uncover varying human-bacteria protein-protein interactions. Of interest, Zhou *et al.* (2013b) proposed a stringent domain-based prediction method. The method first detects the PPIs using the domain-domain interaction approach that employs Bayesian formula (Dyer *et al.*, 2007; as explained in the next section). Then, a layer of assessment is applied; where for each predicted PPI, a score that indicates the strength of each interaction is calculated based on the interacting residues in their interaction interfaces extracted from the 3did database. Using this layer of assessment, the authors claim that the stringent method is better than the conventional one. A different layer of assessment has been proposed by Mahajan and Mande (2017). It employs the Smith-Waterman local alignment-based comparison of bacterial and human proteins with domain-domain interaction template sequences, and it is followed by the calculation of the geometric mean of the similarities for scoring the interaction.

In another human-*M. tuberculosis* PPIs study, Zhou *et al.* (2014) introduced a stringent homology-based method which predicts human-*M. tuberculosis* PPIs from known eukaryote-prokaryote inter-species PPIs. Such stringency takes into account the differences between (1) the structures of eukaryote and prokaryote genes, and (2) the interfaces of intra- and inter-species protein-protein interactions. The authors claimed that the stringent approach performs better than the conventional method that infers human-*M. tuberculosis* interologs from inter-species PPIs.

Uncovering Human-Parasites Protein-Protein Interactions

Studies in this category have frequently explored the interactions between human and *Plasmodium falciparum*, the deadliest *Plasmodium* that causes malaria disease. For detecting the interactions, the homology-, domain-, and structural-based methods have been employed independently by Davis *et al.* (2007), Dyer *et al.* (2007), Lee *et al.* (2008) and Liu *et al.* (2014). In addition, Krishnadev and Srinivasan (2008) have also combined homology- and domain-based methods for the detection, while Wuchty

(2011) applied a random forest classifier to a dataset containing the composition of amino acid triplet classes of interacting proteins in order to obtain more reliable interolog candidates.

Of interest, Dyer *et al.* (2007) applied the Bayesian formula to calculate the likelihood that the host and pathogen proteins interact given their domains. In particular, for host protein H and pathogen protein P that have domain h and p, respectively, the likelihood is computed as follows:

$$\Pr(I(P, H)|D(P, p) \cap D(H, h)) = \frac{\Pr(D(P, p) \cap D(H, h)|I(P, H))\Pr(I(P, H))}{\Pr(D(P, p) \cap D(H, h))}$$

where $I(P, H)$ denotes the event that protein P and H interact and $D(P, p) \cap D(H, h)$ denotes the event that protein P has domain p and protein H has domain h. Each term on the right-hand side can be calculated from intra-species PPIs and the domains present in each of the interacting proteins. If multiple pairs of domains (p_i, h_j) are contained in the pair of proteins, then the likelihood of the interaction is estimated by assuming the independence of domain pairs, which gives the following formula:

$$\Pr(I(P, H)|\cap_i \cap_j (D(P, p_i) \cap D(H, h_j))) = 1 - \prod_i \prod_j (1 - \Pr(I(P, H)|D(P, p_i) \cap D(H, h_j)))$$

The application of expectation-maximization algorithm to calculate this likelihood has also been proposed by Liu *et al.* (2014).

Another particular note from studies on human-*P. falciparum* PPIs is on how the candidate of interactions are further filtered with various biological contexts (Lee *et al.*, 2008; Krishnadev and Srinivasan, 2008; Wuchty, 2011; Liu *et al.*, 2014). These include filtering with: (1) various molecular characteristics of parasite proteins (e.g., the presence of transmembrane domains, signaling peptides and host cell-targeting signals); (2) cellular localization (proteins localized in nucleus or mitochondria are not expected to interact); (3) cellular functions (ubiquitin proteins, DNA polymerases, and splicing factors are not expected to interact); and (4) expression data in the corresponding human tissue and parasite's cell cycle stage (e.g., host proteins in liver tissue and parasite proteins in the sporozoite stage; host proteins in erythrocyte and pathogen proteins in merozoite stage).

Discussion

In the previous section, we illustrated the application of the workflow for HP-PPI prediction to investigating human-pathogen PPIs. One important observation is that a particular strategy may or may not be useful for prediction involving a particular type of pathogen, or a particular type of interaction. For example, the Bayesian method proposed by Dyer *et al.* (2007) may not be useful for investigating human-HIV interactions due to the absence of viral domains; instead, the utilization of ELMs or SLiMs would be more appropriate to capture host-viral interactions, such as works of Evans *et al.* (2009) and Becerra *et al.* (2017). For another example, we ought to utilize tools for predicting the presence of extracellular or trans-membrane domains if we focus on the interactions that drive invasion and intracellular signaling of bacteria or parasites. Hence, knowledge about biological and biochemical contexts would be very valuable when predicting HP-PPI networks (see Sen *et al.* (2016) for further insights).

Nonetheless, like other integrative genomic studies, computational HP-PPI studies are still in their infancy and many issues still need to be addressed before they become fruitful. First, each HP-PPI detection method comes with its own limitation. Sequence, domain, and motif similarity-based methods tend to produce many false positives; structure similarity-based methods are constrained by the available protein structures in the database; supervised learning methods lack definitive noninteracting datasets; lastly, association rule learning methods are limited by a small fraction of known interactions.

To cope with the high number of false positives produced by sequence-, domain- and motif-based similarity methods for detecting PPIs, the standard method being used is by filtering detected interactions. Various types of filters have been highlighted in the previous section, and filters based on biological context and structural information are the most popular ones. Another strategy to prevent the high number of false positives is to use a stringent criterion for PPI resources being used for comparison. For example, when predicting the interaction between human and bacterial proteins, we may follow the approach proposed by Zhou *et al.* (2014) which only uses known interactions between eukaryotic and bacterial proteins as gold standard PPIs.

Meanwhile, issues with scarcity and unavailability of gold standard data (in other words, missing data) for learning-based approaches have been resolved mainly by utilizing knowledge of homologous genes. Kshirsagar *et al.* (2012) have demonstrated that imputation of missing data for GO annotations and gene expression features with techniques that utilize homolog or cross-species information outperform other imputation techniques. In particular, they applied two phases of imputation: (1) cross-species information integration and (2) modeling-based imputation. The first phase is able to transfer a large number of cross-species attributes, but it still leaves missing values of gene expression for proteins whose homologs are unknown. The second phase estimates the rest of missing values by using a LASSO regularization technique. Mei (2013) also used homolog information features for missing data and demonstrated that prediction with a probability weighted ensemble learning that only utilizes homology features for training and testing has promising results, indicating the effectiveness of the approach. Mei and Zhu (2014a) further demonstrated the effectiveness of transferring homolog features as the second instance of proteins in predicting cross-species protein interactions using a multi-instance AdaBoost method.

As it is mentioned earlier, the lack of verifiable negative feature datasets for noninteracting protein pairs is also another problem in supervised machine learning methods for HP-PPI prediction. Assuming that the number of interacting host-pathogen protein pairs is far less than the number of noninteracting ones, such that the probability of randomly picking positive interaction is close to zero, it is very common to randomly choose the noninteracting pairs from the set of protein pairs with no interaction evidence. Nonetheless,

Yu *et al.* (2010) noted that the choice of noninteracting proteins in the training data may greatly influence the accuracy of the classifier or predictor due to the bias towards the interactions involving hub proteins in the positive dataset. To prevent the bias, Yu *et al.* (2010) performed a balanced random sampling that ensures each protein appears in the positive and negative datasets with the same frequency. In another study, Mei (2013) claimed that excluding the pairs from the same sub-cellular localization also allows the construction of a reliable and unbiased classifier. Furthermore, Eid *et al.* (2016) proposed the use of a dissimilarity threshold for alignment between pathogen protein pairs to pick unlikely interactions as negative examples. In particular, if pathogen protein y is known to interact with host protein h , and x and y are dissimilar, then we conclude that x is unlikely to interact with h .

In addition to missing data and the construction of negative dataset, practices of validating machine learning models have also been criticized. Note that the notion of validation here is different from the validation of predicted HP-PPIs in the presented workflow – validation in machine learning approach assesses how well a model has been trained, while validation in the workflow assesses the biological significance of predicted interactions. Abbasi and Minhas (2016) questioned the effectiveness of K-fold cross-validation for estimating the generalization ability of host-pathogen PPI prediction for proteins with no known interaction. In particular, they highlighted the possibility of K-fold cross-validation for not preventing both similarity and redundancy between training and testing examples within a fold, i.e., a protein in a test example in a fold can occur as part of another example in training. To resolve this, they proposed an alternative evaluation scheme called leave one pathogen protein out (LOPO) and demonstrated that it was more effective in modeling HP-PPI predictors. In relation to this proposed method, they have also proposed new performance metrics that include true hit rate (THR), false hit rate (FHR) and median rank of the first positive prediction (MRFP), which were claimed to be more intuitive for biologists.

Another issue related to learning-based methods is feature representation, which is still an ongoing research area for bioinformatics overall. As mentioned earlier, k-mer composition – especially the conjoint triad – has become one of the most popular features being used. Nonetheless, the study by Yu *et al.* (2010) has highlighted a pitfall in using such simple sequence features since some hub proteins that appear many more times in the positive set than the negative sets will lead to unrealistic accuracy. This is demonstrated by the performance of SVM learning method on balanced random sampled negative interaction datasets that is lower than the performance on purely random negative interaction sampled datasets. In another study related to human-virus interactions, Barman *et al.* (2014) demonstrated that domain-domain association appears to be the best descriptor among 44 descriptors that include amino acid composition and association with disordered regions. In a more recent study, Jindal *et al.* (2016) have explored the usefulness of graphlet degree vector (GDV), a network feature that represents the similarity of local topological structure between proteins in a host PPI. Such feature is claimed to increase the performance of stochastic gradient descent (SGD) and soft confidence-weighted (SCW) learning methods.

Finally, the major issue in applying integrative genomic approaches for predicting HP-PPIs is the fact that the overlap between predicted interactions from different approaches tend to be small, as exemplified by the human-HIV studies we discussed previously. Abstract models (e.g., the definition of the motif and the formulation of the learning method), filtering methods, and types of features extracted for interacting protein pairs and their interaction interfaces – all of them easily influence the outcome of the prediction. This issue is not yet resolved and should be paid attention to in the future.

Future Directions

Tremendous accumulation of biological data – including genomic data, 3D protein structures, and gold standard experimental HP-PPI data – could be expected to continue and their quality will be improved. On the other hand, the performance of integrative bioinformatics approach for predicting HP-PPIs would be enhanced and related algorithms are expected to be more accurate and effective. Thus, in the presence of cheaper genome data but the absence of costly gold standard protein-based interactome data, predictive methods provide an alternative to obtain valuable insights about the nature of specific HP-PPI networks, especially in the area of human infectious diseases. Hence, the development of bioinformatics tools and pipelines that allow a routine prediction and exploration of HP-PPI networks by life scientists would be expected in the next few years.

In addition to biological insights, the ultimate goal of uncovering HP-PPI networks is to drive the development of network medicine and personalized medicine for infectious diseases. Investigations of HP-PPI networks are expected to aid the discovery of new biomarkers and therapeutic targets based on gene essentiality and some other network principles. For example, it will assist the design of multiple drug combinations that target disease modules and re-route metabolic activity to compensate for the lost functions during a disease state (Barabási *et al.*, 2011). In relation to personalized medicine, a challenging problem in the prediction of HP-PPI networks is to take into account genetic make-up of both host and pathogen. A recent study by Recker *et al.* (2017) has clearly demonstrated the importance of both host and pathogen factors in determining the outcome of infections by *Staphylococcus aureus*. Hence, the ability to incorporate the host and pathogen genetic variations into HP-PPI network models should help us to understand further on why some pathogens become more virulent, or why some pathogens do not affect the host. Of interest, we like to uncover how small genetic changes could impact the activation or deactivation of disease modules. To some extent, this means that we attempt to measure the virulence of pathogens as defined by Casadevall and Pirofski (1999), i.e., the capacity of microbes to cause damage according to the interplay between unique host and pathogen properties. Such understanding will further drive the development of personalized medicine for infectious diseases, which has become more feasible these days.

Closing Remarks

We have presented recent progress in the development of computational prediction of HP-PPIs. Explicitly, we have differentiated two major principles in detection methods used in the prediction workflow for new HP-PPIs, i.e., similarity-based and learning-based methods. Case studies on human infectious diseases and some insights obtained from the studies are illustrated. Several issues on the approaches and some proposals for addressing the issues, mainly for learning based methods, are highlighted. One challenging problem to be resolved is the inconsistency of predicted HP-PPIs given by different methods. Nonetheless, while efforts for improvements are being made, existing workflows may be utilized to guide HP-PPI experimentation as well as gain further insights into principles underlying host-pathogen interactions. Finally, enhancements to the methods and overall workflows may allow us to advance the development of network and personalized medicine related to infectious diseases.

Biographical Sketch

Dr. Fransiskus Xavierius Ivan is a Research Fellow in the School of Computer Science and Engineering, Nanyang Technological University (NTU), Singapore. He received Ph.D. in Computations and Systems Biology, Singapore-MIT Alliance (SMA) Programme from NTU in 2014, Master of Computing and Information Technology from the University of New South Wales (UNSW) in 2008, and Bachelor of Science in Mathematics from Bogor Agricultural University in 1999. His research interest is interdisciplinary life science, which is not limited to Bioinformatics, Genomic Data Science, Computational Systems Biology, and Computational Host-Pathogen Interactions. He has published in experimental and computational life science journals and conferences, including *Genomics*, *Functional Integrative Genomics*, *IEEE Engineering in Medicine and Biology Conference (EMBC)*, and *ACM Conference on Bioinformatics, Computational Biology, and Health Informatics (ACM BCB)*. Dr. Ivan has actively collaborated with scientists from various backgrounds, including Life Science and Biomedical Science.

Dr. Jie Zheng is a tenure-track assistant professor of School of Computer Science and Engineering, Nanyang Technological University (NTU), Singapore. He received PhD in 2006 from the University of California, Riverside and his B. Eng (honors) in 2000 from Zhejiang University in China, both in Computer Science. Before joining NTU in 2011, he was a research scientist at the National Center for Biotechnology Information (NCBI), National Library of Medicine (NLM), National Institutes of Health (NIH), USA. His research interests are Bioinformatics, Computational Systems Biology and Genomics, aiming to develop novel algorithms and *in silico* models to help answer Biomedical questions (e.g. how are cell fates decided in cancer and stem cells). He has published in top-tier journals such as Genome Biology, Molecular Biology & Evolution, Nucleic Acids Research, Bioinformatics, PLoS Computational Biology, etc. While trained as a Computer Scientist, Dr. Zheng maintains active and long-standing collaborations with Life Scientists.

Dr. Vincent T.K. Chow is a medical virologist and molecular biologist who graduated with MD, PhD, MBBS, MSc and FRCPath qualifications. Currently, he serves as Associate Professor and Education Director of Microbiology, and Principal Investigator of the Host and Pathogen Interactivity Laboratory at the Yong Loo Lin School of Medicine, National University of Singapore (NUS). Since 1996, he established the Human Genome Laboratory that has isolated and characterized several novel human genes and proteins. Dr. Chow previously served as President of the Asia-Pacific Society for Medical Virology, as well as Chair of the Virology Section of the International Society of Chemotherapy. His laboratory has published over 250 articles in international refereed journals, and has presented over 260 conference papers. He has received several awards (including the Murex Virologist Award, the Special Commendation Award and Faculty Research Excellence Award from NUS, the Singapore Society of Pathology – Becton Dickinson Award, and the Chan Yow Cheong Oration at the 6th Asia-Pacific Congress of Medical Virology). His recent research interests focus on the molecular genetics and infectious of influenza pneumonia and of hand, foot and mouth disease, specifically on the cellular, molecular, and viral pathogenesis of severe influenza and enterovirus 71 infections.

Dr. Kwoh Chee Keong is in the School of Computer and Science Engineering, Nanyang Technology since 1993. He received his Bachelor degree in Electrical engineering (1st Class) and Master in Industrial System Engineering from the National University of Singapore in 1987 and 1991 respectively. He received his PhD from the Imperial College, University of London in 1995. His research interests include Data Analytics, Data Mining, and Graph-Based Inference; applications areas include Bioinformatics and Biomedical Engineering. He has done significant research work the research areas of Bioinformatics and Computational Biology. He has been active as organizing member, referee and reviewer for a number of premier conferences and journals. Dr. Kwoh is a member of The Institution of Engineers Singapore, Association for Medical and Bio-Informatics, Imperial College Alumni Association of Singapore (ICAAS). He has provided many service to professional bodies, and the Singapore and was conferred the Public Service Medal, the President of Singapore in 2008 and the National Day Award Ministry of Education (Long Service Medal) in 2016.

Comparative Genomics Analysis

Hui San Ong, Perdana University, Selangor, Malaysia

Introduction

Deoxyribonucleic acid (DNA) is a nucleic acid that encodes the genetic information required to carry out activities in all living organisms. A DNA molecule comprises of two strands, each run in the direction of 5' to 3' and are antiparallel. Both strands pair based on Watson-Crick complementarity; adenine (A) binds to thymine (T) while guanine (G) binds to cytosine (C). A genome can be defined as a complete collection of an organism's DNA, inclusive of the genes (the coding regions) and noncoding DNA. Genomics, on the other hand is an interdisciplinary field concerned with the study of the genes and intergenic regions as well as their structures, function and evolution.

The availability of genomics information from living organisms has led to the empowerment of comparative genomics analysis. The goal is to use related genomes en masse to achieve a better understanding of every individual genome in a dataset. It involves the comparison of more than one genome to uncover the similarities and differences between them. Comparison can be conducted for the entire genomes or the syntenic regions of various species or for various strains of the same species (Wei *et al.*, 2002). However, the scope of comparisons varies, as it can be carried out between the same species or across different kingdoms of living organisms. For example, the study of HSP90 chaperone family was carried out in Archaea, Bacteria, Protista, Plantae, Fungi and Animalia (Chen *et al.*, 2006). There are three distinct levels where the genome comparison can be carried out; in order to gain different viewpoint on an organism, (i) genomes structures at DNA and gene levels, and overall nucleotide statistics, (ii) coding regions and (iii) noncoding regions, including the prediction of the regulatory elements (Wei *et al.*, 2002; Loots *et al.*, 2002). In contrast to the former two, studies on noncoding regions are rather at infancy and much work needs to be done. It is only until late 20th century that we started to understand that regulatory sequences in noncoding regions play essential roles in the post-transcriptional processes (Wedemeyer *et al.*, 2000; Mazumder *et al.*, 2003).

Comparative genomics can be dated back to 1984 through the efforts led by Professor Wimmer to compare different virus genomes. The comparison was made between several animal picornaviruses and cowpea mosaic virus, a plant virus that causes the "mosaic" pattern on plant leaves (Argos *et al.*, 1984). Two years later, a large-scale study was carried out between the varicella-zoster virus that causes chickenpox in humans and the Epstein-Barr virus that is associated with diseases such as gastric cancer, nasopharyngeal carcinoma and Hodgkin's lymphoma (McGeoch and Davison, 1986). Ever since then, this approach has been employed extensively and its application encompasses various fields such as agriculture (Sharma *et al.*, 2014; Sorrells, 2006; Wang *et al.*, 2017), evolutionary study and disease study (Alfoldi and Lindblad-Toh, 2013).

The main objective of this article is to provide the readers an overview of how bioinformatics is applied to carry out comparative genomics, with a focus on agriculture and biomedical research. It begins with a brief historical background and provides the current status on some notable genome sequencing projects. This is not meant to serve as an exhaustive dossier on comparative genomics, but rather to serve as a guide on the topic from the application perspective.

Background

The Past and Present: From Sequence to Genomes

The earliest bacterial genomes *Haemophilus influenza* and *Mycoplasma genitalium* (Fleischmann *et al.*, 1995; Fraser *et al.*, 1995) were fully sequenced in 1995 and 8 years later, the first human genome sequencing project was concluded (International Human Genome Sequencing, 2004). Since then, several teams have taken on the challenge of initiating ambitious genome sequencing projects, such as the 100,000 Genomes Project by Genomics England to sequence genomes of 100,000 patients with rare disease, registered with the National Health Service (NHS) (England, 2016); another is the GenomeAsia 100 K project to sequence 100,000 individuals in the Asian population (see Relevant Website section).

The rapid surge in the number of sequencing projects has led to the generation of massive amount of data, evidenced by the increment of sequencing data depositions in the Sequence Read Archive (SRA) (Leinonen *et al.*, 2011) at National Center for Biotechnology Information (Fig. 1). Many other public databases that cater for the specific projects based on the organism being sequenced have also been developed, for instance the Ensembl Genomes (Hubbard *et al.*, 2002), Mouse Genome Database (MGD) (Bult *et al.*, 2008), Maize Genetics Database (MaizeGDB) (Lawrence *et al.*, 2004), UCSC Genome Browser Database (Karolchik *et al.*, 2003) and other specific human disease-related databases, such as The Cancer Genome Atlas (Cancer Genome Atlas Research, 2008) and International Cancer Genome Consortium (Zhang *et al.*, 2011).

These efforts exemplify how the sequencing projects have progressed at a rapid speed, largely owing to the vast reduction in the sequencing cost, which stands at USD 0.012 per megabase as of 31st July 2017 (Wetterstrand, 2017). In the last five years (from 1st August 2013 to 1st August 2017), we have seen publications with the word "genome sequencing" (in the title/abstract) recorded in the PubMed database increase by two folds; with a latest a total of 13,314 articles published. During the

Fig. 1 The graph shows the growth in the Sequence Read Archive (SRA) database that stores raw sequencing data from high-throughput sequencing platforms from year 2008 to the present. The data used to plot this graph were extracted from Sequence Read Archive at <https://www.ncbi.nlm.nih.gov/Traces/sra>. The graph was built using R version 3.4.0. Reproduced from Leinonen, R., Sugawara, H., Shumwayand, M., International Nucleotide Sequence Database Collaboration, 2011. The sequence read archive. *Nucleic Acids Res* 39, D19–D21.

same time period, publications with the phrase “comparative genomics” in the title or abstract surged from 3546 articles to 5560 articles, an increment of approximately 57% from the year 2013. These figures indicate that one of the driving forces behind comparative genomics is the growth in the number of genome sequencing projects that provide the required genomics data.

Methods in Comparative Genomics

The process in comparative genomics frequently involves the alignment of DNA sequences; such as the use of pairwise alignment (e.g. Needle and Water [Needleman and Wunsch, 1970](#); [Smith and Waterman, 1981](#)) to detect closely related genes. An extension of this sequence alignment is multiple sequence alignment (MSA) such as Clustal Omega ([Sievers et al., 2011](#)) and T-coffee ([Notredame et al., 2000](#)) where it can be used to detect conserved regions through the alignment of three or more sequences. Housekeeping genes are examples of regions in a genome that tend to be highly conserved and evolve slower than other genes such as the tissue-specific genes ([Zhang and Li, 2004](#)), mainly due to their roles in the maintenance of basic cellular functions and are essential for the existence of a cell.

Homology is another crucial term that is frequently integrated into genomics study. The detection of homologous genes is of fundamental importance in many fields of biology, particularly in comparative genomics. Homology refers to a relationship between genes due to a common ancestry and it can be applied in two major contexts, depending on whether the genes were separated through a speciation (ortholog) or duplication (paralog) event. Orthologous genes are usually detected using sequence similarity, and a gene is considered as ortholog of each other if they have the highest percentage of sequence similarity compared to others genes. Reciprocal best blast hits ([Ward and Moreno-Hagelsieb, 2014](#); [Horiike et al., 2016](#)) and domain based detection ([Chen et al., 2010](#)) are among the standard protocols used to detect the orthologous genes. Unlike orthologous genes which preserve the same function throughout evolution, paralogous genes are the new genes that diverged after duplication events and later evolved into a new function. The procedures used in comparative genomics vary depending on the application, and the general workflow on the commonly used procedures is detailed in [Fig. 2](#).

Applications of Comparative Genomics

Prokaryotes

Mycobacterium ulcerans causes Buruli ulcer, an infectious tropical disease that causes skin ulcers. Although much effort has been invested, the slow growing nature of *M. ulcerans* in experimental conditions has hampered the progress in conventional drug discovery methods. To address this problem, the comparative genomics technique has been deployed by [Butt et al. \(2012a\)](#) to

Fig. 2 General workflow of comparative genomics. It starts with the subject's genome and proteome as input and followed by the information retrieval from KEGG database. The BLAST search (e.g. BLASTP) against the target's proteome will reveal the existence of unique or common (shared) proteins between the subject and the target. Further bioinformatics analysis is often conducted on the proteins of interest.

identify novel therapeutic candidates against *M. ulcerans*, through homology searching of essential targets from twenty different bacteria that have no homology in human host. The group successfully discovered a total of 236 proteins based on these criteria as the potential drug and vaccine candidates against *M. ulcerans*. The comparison was done using a series of computational workflows which includes the homology blast search and analysis of host and pathogenic metabolic pathways (Butt *et al.*, 2012a).

The study carried out on *Salmonella Typhimurium* LT2 and *Mycoplasma genitalium* were based on the similar approach to *M. ulcerans*, that is focusing on the identification of essential targets in the bacterial pathogens but have no homology in the human host. These studies are coupled with metabolic pathway analysis in order to pinpoint the unique biological pathways that are present in *S. Typhimurium* LT2 (Samal *et al.*, 2015) and *M. genitalium* as compared to the *Homo sapiens* (Butt *et al.*, 2012b). The workflows, which include the drug targets prioritization and homology modelling have successfully identified 13 proteins as vaccine candidates in *S. Typhimurium* LT2 (Samal *et al.*, 2015). *M. genitalium* is another human parasitic pathogen that is affiliated with sexually transmitted diseases. Hence, *in silico* comparative genomics is being employed because conventional drug discovery process is costly and bear few drug targets. This comparison against human host has identified 67 non-homologous essential proteins of *M. genitalium*, which could serve as potential drug design and vaccine targets against *M. genitalium* (Butt *et al.*, 2012b).

Concretely, comparative methods are employed to pinpoint genes of essential function amongst the pathogenic bacteria, even more so when there is an increasing emergence of reported antibiotic-resistant pathogenic microorganisms (Choudhury *et al.*, 2012; Martinez, 2008). In view of this, Glass *et al.* (2002) compiled a list of essential attributes of a good drug targets in the bacteria genomes, which includes the target (i) being essential for the disease, (ii) unique to the bacteria and significantly different from its corresponding orthologous genes in human and (iii) present in key pathogenic bacteria (Glass *et al.*, 2002). As proposed by the former examples, target selection is mainly done using computational approaches, for example, comparison of pathways, sequence and structural homology as well as cluster and motif analysis (Gerstein, 2000; Rosamond and Allsop, 2000; Gerstein and Jansen, 2000).

Genome comparison can also be made with the aim to identify species-specific features or single-copy (unique) genes of an organisms. In the context of comparative genomics, some of the unique genes can be referred as the genes with no homolog, even with its closely related species (Llorente *et al.*, 2000; Ong *et al.*, 2012). These genes can be used to provide insights into the niche adaptation of the specific phenotypes (Kahlke *et al.*, 2012) and virulence factors. *Helicobacter pylori*, a gram negative bacteria that colonizes gastric epithelium and causes a persistent inflammatory response (Ruggiero, 2010) is an example of bacteria that possess such unique feature in their genetic makeup. Given its distinctive role in pathogenicity, genome comparison was carried out between *Helicobacter pylori* and its two pathogenic counterparts; *Haemophilus influenza* and *Escherichia coli*. The work has successfully contributed in the identification of species-specific features such as acid tolerance and outer membrane family proteins, which are

crucial for the bacteria's colonization in acidic environment (Huynen *et al.*, 1998; Matsuo *et al.*, 2017). These outer membrane proteins were used by *H. pylori* to attach to the host's gastric epithelial cells (Matsuo *et al.*, 2017).

In another similar approach, cross-species comparison was conducted by comparing *Vibrio harveyi* CAIM 1792 with its related genomes to resolve their phylogeny relation as well as to discover unique regions that served to differentiate these strains (Espinoza-Valles *et al.*, 2015). These unique traits include the regions that encode for transcriptional regulator, LysR, which was described to be associated with pathogenic activity, quorum sensing and motility (Maddocks and Oyston, 2008). *V. harveyi* CAIM 1792 is of interest because this marine bacterial strain causes mortality in shrimp (Soto-Rodriguez *et al.*, 2010; Moriarty, 1998), and therefore the discovery of virulence genes in this strain is crucial.

Agricultural Animals and Plants

Agriculture is one of the most important sectors that provides food supply, as well as industrial raw materials. Farm animals, for example, have been bred by targeting on their desirable traits, such as disease resistance and their rapid growth. The general location on a chromosome for a gene that expresses a particular trait is known as quantitative trait locus (QTL). Dairy cattle for instance, has at least 30 QTLs that were likely to be involved in the milk production traits (Chamberlain *et al.*, 2007). An animal or plant species with favourable QTLs will have strong advantage over the other species; and this serves as the basis for the urgency of comparative genomics study to be carried out. This is mainly to increase the production of the agricultural commodities. The aim is to discover genes that are related to disease resistance, breed-specific quantitative loci along with phenotypes of agricultural relevance, known as economic trait loci (ETL) (Womack and Kata, 1995; Womack, 1998). The identifications of ETLs in animal pedigrees are crucial given that they are important for the improvement and production of livestock.

Turkey and chicken are important poultry; they are raised mainly for their meat and eggs production and thus have significant contribution in agricultural economy. Due to their importance in daily food consumption, numerous scientific efforts (Reed *et al.*, 2005; Chaves *et al.*, 2006; Reed *et al.*, 2006; Wallis *et al.*, 2004) have been concerted on aspects that would be beneficial to the industry. Comparative works for instance have successfully established the cytogenetic map between the turkey and chicken that allowed for the transfer of genetic data from chicken to turkey and prediction of novel loci for target marker development (Griffin *et al.*, 2008). Besides chicken-turkey comparison, the comparison is also being extended to other genomes, including human genome (International Chicken Genome Sequencing, 2004).

Identification of orthologous genes is one of the common procedures in comparative analysis. Once the orthologous genes have been defined, the subsequent step is the identification of the conserved chromosomal regions that will lead to the generation of comparative map (Burt, 2002). If two genes are located on the same chromosome, the two are known as syntenic. The construction of cattle-human comparative map (Larkin *et al.*, 2003) assists in the adding of the cattle genome to the existing multispecies comparative genome studies, which is also inclusive of goat (Schibler *et al.*, 1998), pig (Pinton *et al.*, 2000; Ma *et al.*, 2011), and horse (Caetano *et al.*, 1999).

Besides agriculture livestock, identification of quantitative trait locus (QTLs) is also important in increasing crops yield, its tolerance against environmental stress and disease resistance, which would involve the construction of genetic maps of the crop species. To exemplify this, Hwang *et al.* (2006) successfully formulated a fine genetic map near Rsv4 gene in soybean by comparing against the genome of closely related model, legume *Lotus japonicas* (Hwang *et al.*, 2006). Rsv4 gene has profound economic value due its ability to confer resistance against all seven Soybean mosaic virus (SMV) strains (Ma *et al.*, 1995). Soybean [*Glycine max* L. (Merrill)] is one of the major sources of edible oil and proteins and it is under severe threat from SMV that could affect its production worldwide (Hill and Whitham, 2014). Following the formulation of this genetic map near Rsv4 gene, the researchers are able to derive a new biomarker, AW307114A from the soybean expressed sequence tags (ESTs). This newly discovered marker is important because it is more closely linked to Rsv4 resistance gene in the soybeans (Hwang *et al.*, 2006) than the previously discovered biomarkers.

Bacterial wilt (BW) is yet another plant disease caused by *Ralstonia solanacearum* that affects pepper, tomato and eggplant (Hayward, 1991). To overcome this, researchers resequenced the plants that harbour resistance traits towards BW, in this case the pepper plant YCM344 (Kang *et al.*, 2016). Using the comparative analysis against the pepper reference genome sequence (version 1.55), they have successfully identified single nucleotide polymorphisms (SNP) that have the potential to cause BW resistance in pepper plant. Not only that, they could also pinpoint genomic regions of these SNP to be homologous to the known resistance genes in the tomato genomes, exemplified yet again by the use of comparative analysis to identify conserved regions across different genomes.

Jute (*Corchorus* sp.) is one of the pivotal sources of natural fibre, with the advantages such as high tensile strength, moderate heat resistance and biodegradable. Given that jute production has profound economic value, genomics comparison was carried out on two species of jute (*Corchorus olitorius* and *Corchorus capsularis*) against 13 others genomes including *Arabidopsis thaliana* and *Glycine max* (Islam *et al.*, 2017). Subsequent identification of homologous genes has led the team to propose a model for bast fibre biogenesis in jute (Islam *et al.*, 2017). The understanding of molecular basis of the fibre biogenesis enabled improvement to the breeding strategies of jute to meet the increasing demand of natural fibres in industry, as the annual global production of jute is up to 2.821 million tonnes for year 2014/15 (Food and Agriculture Organization of The United Nations, 2016).

Rice (*Oryza sativa*) is the staple food in Asia and the productions of rice are among the highest in Asian populations. A number of comparative genomics studies have been conducted on rice. For instance, the comparison between rice and *Arabidopsis* genomes using the phylogenetic comparisons reveals that certain families that are involved in the auxin homeostasis and plant

development in Arabidopsis are missing from the rice genome (Nelson *et al.*, 2004). Another comparison of structural variation was conducted between rice and its closest relative in the genus *Oryza* (Hurwitz *et al.*, 2010). Together, this has resulted in the detailed catalog of structural variation across the *Oryza* family that can be used for forthcoming works in genome evolution, speciation, domestication and novel gene discovery (Hurwitz *et al.*, 2010).

Comparative genomics has showcased significant improvement in the plants yield production. This is of much dire urgency, as better yield of crops production would ensure better management of the famine outspread worldwide, with estimates about 795 million people from the 7.3 billion people in the world were affected from persistent undernourishment (Food and Agriculture Organization *et al.*, 2015)

Animal Models for Human Disease

From historical perspective, biologists remarkably benefited from the study of animals. Animal models (Perlman, 2016; Jiminez *et al.*, 2015; Schofield *et al.*, 2011; Iannaccone and Jacob, 2009; Shin and Fishman, 2002) are often used to get a better understanding on the diseases that are associated with human. For instance, nematode (*Caenorhabditis elegans*) is used as a model for studies such as in cancer research (Kyriakakis *et al.*, 2015) and in host-microbiome interactions at the apical surface of epithelial cells in the intestine (Pukkila-Worley and Ausubel, 2012). This interaction study is important because the immune defense system must be able to distinguish between pathogens and the harmless bacteria that are present in the mammalian intestine, in order to combat infection.

The use of human disease models in understanding the fundamental pathophysiology of a disease and the breakthrough of new therapeutic, signifies the need for comparative studies. For instance, the study of mouse genome involved the identification of QTLs for blood pressure that are known to contribute to hypertension (Wright *et al.*, 1999). This breakthrough has served as a precursor for the development of novel comparative genomics map for “candidate hypertension loci” in human based on the QTLs translation between rat model and human (Stoll *et al.*, 2000). It has then resulted in the prognostication of 26 chromosomal regions in human that are plausible to harbour hypertension genes (Stoll *et al.*, 2000), and thus can potentially be used for the development of new therapeutics.

Although rat and mouse remain the leading models to decipher the genetic basis of human diseases, zebrafish is yet another excellent model for human disease. This is mainly attributed to its optical clarity during embryogenesis, high productivity of large clutches of embryos and short generations time (Detrich *et al.*, 1999). On top of that, due to high genomic content similarity shared between zebrafish and human (approximately 70% the genes are orthologues) (Howe *et al.*, 2013), it offers huge opportunities for comparative analysis between these two genomes. Some of the applications of zebrafish as a model for better understanding of the human diseases would be the study of cardiovascular disease (Sehnert and Stainier, 2002; North and Zon, 2003), muscle disease (Guyon *et al.*, 2007; Kunkel *et al.*, 2006) and aging process (Keller and Murtha, 2004).

Animal models also served as valuable tools to study the biology and genetic aspects of human cancers, as well as for preclinical study of anti-cancer therapeutics (LeGendre-McGhee *et al.*, 2015; Steele *et al.*, 2005; Ruggeri *et al.*, 2014). Therefore, it is crucial to have animal data to be evaluated in the context of human cancers. Some initial cancer studies leverage on comparative genomics to identify orthologs of cancer genes (Pickeral *et al.*, 2000; Makalowski *et al.*, 1996), such as for the study of Wnt signalling pathway (Katoh and Katoh, 2005a,b). While other studies carry on with further analysis to define the syntenic region between the rat and human genomes and this helps to uncover the chromosomal regions for tumor and metastasis in the rat that are involved in human prostate cancer (Datta *et al.*, 2005).

In short, although human and animal models may have different physical appearance, but both share a certain degree of similarities in their genomes. It is these “similarities” that could give important clues on the development of the diseases in human and afford us an opportunity to treat these diseases more effectively. In fact, researchers are now able to find better treatment of human disease by recreating the human diseases in animal models, ensuring a better quality of life ever since for human.

Closing Remarks

The fundamental basis of comparative genomics is to identify the genes of interest that control traits variation and this is made possible through the ability to compare and contrast between one organism to another organism. Aided with the integration of genomics analysis, this translation is an exciting notion in gaining the momentum for the breakthrough in gene discovery for all domains of life, either for single-celled or multicellular organisms. The resulting genomics information is able to provide insights into the biology of an individual genome, benefitting the advances in human disease related study and greater yield improvement in agricultural animals, plant and crops.

Introduction

SNPs have emerged as important biomarkers to monitor disease prognosis and diagnosis. A SNP is a single base pair (bp) change either an insertion/deletion/substitution at a specific locus, with rare allele frequency usually $> 1\%$. These variations in DNA sequences may alter the genetic code and result in disease conditions or undesirable traits. Historically, a number of different SNP typing approaches have been used in both research and clinical laboratories (Srinivasan *et al.*, 2016). Presently, there is no single SNP genotyping method that is ideal for all research and/or clinical laboratory applications. Commonly used current chemistries include hybridization, primer extension, and cleavage methods coupled to various detection systems (Srinivasan and Batra, 2014). A multitude of innovations in these reagents and instrumentation have supported the initiation of the Human Genome Project and have led to more advanced technologies some of which are discussed in this review. However, the advanced technologies require a wide variety of algorithms for SNP detection from the raw data generated which is not crucial for the conventional methods. Thus we have categorized the SNP genotyping technologies into approaches that may or may not require computational algorithms for SNP detection as below.

Methods That do not Require Complex Computational Analysis

Amplification Refractory Mutation System (ARMS)

ARMS is an allele-specific polymerase chain reaction (PCR) for the detection of single base changes based on the use of sequence-specific PCR primers that allows amplification of template DNA only when the target allele is present. Thus, an ARMS primer can be designed specifically to amplify a specific member of a multi-allelic system. After PCR, the patterns of the PCR products (such as differences in length) allow differentiation of the alleles (Newton *et al.*, 1989).

High-Resolution Melting (HRM) Curve Analysis

HRM analysis is the technique introduced in 2003 to determine whether two PCR amplicons have identical sequences in the presence of a fluorescent reporter dye. Following amplification, the amplified product is exposed to an increasing gradient of temperature to reduce and denature the helicity of the double-stranded oligonucleotide, releasing the fluorescent dye (Montgomery *et al.*, 2007). Once released, the dye undergoes a conformational change that reduces the amount of fluorescence produced and a thermocycler will record the fluctuations in fluorescence and produce a melt-curve unique to the amplicon sequence analysed. HRM technique thus can compare

the similarity of two amplicons by the melting curve of each oligonucleotide, length, and primary structure (Hjelmso *et al.*, 2014). The weak A-T bond is disrupted at a lower temperature than the G-C bond, and therefore, A-T-rich regions of the amplicon denature at lower temperatures than the G-C-rich regions (Wittwer *et al.*, 2003). The distribution of these A-T- or G-C-rich regions of the oligonucleotide dictates the resulting melt curve and can be used to compare the similarity of amplicons from multiple samples. Although, a simple, cost effective technique, SNPs at GC rich regions are difficult to detect as they introduce additional melting domains into the melting curve and only a small number of SNPs can be multiplexed at one time (Venables *et al.*, 2014).

Restricted Fragment Length Polymorphism (RFLP)

RFLP is a common choice of genotyping in regular laboratories for genetic association studies. RFLP is based on the technique that differentiates SNPs by analysis of patterns derived from cleavage of amplified DNA fragments by restriction enzymes (Chuang *et al.*, 2008). The samples may yield different sized fragments at the SNP site due to either creation or loss of a restriction endonuclease site because of the change in the genomic DNA (Awasthi *et al.*, 2014). To discriminate SNP by this assay, the restriction enzymes must be unique and recognize only one of the SNP containing sequences. This technique is a simple cost-effective method but requires large amount of sample DNA and manual mining for restriction enzyme sites is challenging and cumbersome (Ding *et al.*, 2017).

Invader Assay

Invader assay developed by Third Wave Technologies, Inc. uses fluorescence resonance energy transfer (FRET) detection and does not involve PCR, restriction digestion, or gel electrophoresis. The technology relies on the specificity of Cleavase® enzymes, that recognize and cleave structures that form when the 3' end of an upstream "invading" oligonucleotide overlaps the hybridization site of the 5' end of a downstream oligonucleotide probe by at least 1 bp (Hayashi *et al.*, 2017). This activity enables detection of single-nucleotide mismatches immediately upstream of the cleavage site on the downstream DNA strand because mispairing results in the formation of a noninvasive structure that the enzyme does not recognize as a cleavable substrate. The generation of the proper enzyme substrate is dependent on base-pairing at a critical position between the two oligonucleotides and the target nucleic acid, which provides the ability to discriminate single-base changes.

Single-Strand Conformation Polymorphism (SSCP)

SSCP is a simple and sensitive assay for SNP detection and genotyping. The principle is based on the conformation of the single-stranded DNA (ssDNA). In the presence of a single base change, the conformation of the ssDNA is changed and causes shift in the migration of the DNA under non-denaturing electrophoresis conditions. This results in different band patterns for wild type and mutant DNA samples (Choi and Jung, 2017). A simple SSCP involves four steps: 1) a PCR amplification of target DNA sequence, 2) denaturation of the PCR products, 3) self-annealing of the denatured DNA, and 4) detection in mobility difference of the ssDNA molecules under non-denaturing conditions (Gupta *et al.*, 2014). The DNA can be visualized by different mobility shifts by incorporating radio-isotopes, fluorescent dyes, capillary-based or silver staining.

Heteroduplex Analysis

Hetero-duplex analysis is a low-medium high-throughput SNP detection technique. During heteroduplex analysis, the target gene is PCR amplified and the amplified products are then denatured, re-annealed slowly to form four different double-stranded DNA molecules from the two alleles of the gene (Paniego *et al.*, 2015). In the presence of a heterozygous mutation, two homoduplexes comprising of two perfectly complementary strands (mutant-mutant and wildtype-wildtype) and two heteroduplexes, that contain a sequence mismatch or denaturation bubble (mutant-wildtype and wildtype-mutant) are formed (Palais *et al.*, 2005). The re-annealed DNA molecules on re-annealing can be separated by denaturing high-performance liquid chromatography (dHPLC), enzymatic (RNase cleavage assay), electrophoretic methods and chemical cleavage assays. Heteroduplexes can then be analysed by their differential mobility during electrophoresis, which allows the detection of sequence changes in comparison to the wild type (Velasco *et al.*, 2007).

Allele-Specific Hybridization (Taqman Assay)

Allele-specific hybridization is a technique based on discriminating between alleles at SNP using allele-specific oligonucleotide (ASO) probes and exploits the 5' exonuclease activity of DNA polymerases (Gaudet *et al.*, 2009). Allele-specific PCR (AS-PCR) is achieved by PCR by an allele-specific primer rather than direct detection by a probe. Three primers are required, two to match the two alleles at the SNP site and the third to anneal to the opposite strand (Germer and Higuchi, 2003; Dhas *et al.*, 2015). Some of the tools used for designing AS primers are Tetra-primer, Visual-OMP and Primo SNP. Each of the two probes anneals to one allele to create a stable structure that would lead to its degradation by DNA polymerase, but when it anneals to the other allele, it forms a structure that is less stable so that the probe gets pushed off the template without being PCR amplified. A recent extension of the allele-specific expression is quantification of the allele-specific expression at mRNA level by fluorescence *in situ* analysis in a single-cell. Although simple and effective, the TaqMan assay requires substantial optimization and probe design remains largely empirical that makes it less preferable for large studies.

Allele-Specific Single-Base Primer Extension (AS-SBE)

AS-PCR makes use of the difference in extension between primers with matched and mismatched 3' bases. AS-PCR requires two primers that anneal to the target with their 3' bases matching the two alleles of an SNP. The allele-specific primers are labelled to enable their identification (Kisaki *et al.*, 2010; Balschun *et al.*, 2011). Allele-specific expression (ASE) can be conducted *in situ* on a chip when two allele-specific primers are anchored at different loci. SBE is considered to have a superior discrimination compared to ASE and is dependent on the sequence surrounding the polymorphism.

Oligonucleotide Ligation Assay (OLA)

OLA is a DNA dependent amplification that uses a set of four oligonucleotides, in the presence of a thermostable Taq DNA ligase, to detect SNP alleles. Any nucleotide variation at the ligation junction can be detected using a fluorescent or biotin labelling method (Dokuta *et al.*, 2013; Mutsavangwa *et al.*, 2014). The ligation occurs only when the 3' detector nucleotide is complementary to the SNP nucleotide. Software such as GeneMapper are used for analyzing the raw data and calling SNP genotypes. Two fluorescent peaks in an electropherogram represents two alleles for a specific SNP (Tobler *et al.*, 2005). A variation of this technique was recently reported and known as Heated OLA that uses a thermostable ligase and cycles of denaturation and hybridization for ligation and SNP detection (Beck *et al.*, 2014).

Mid and High-Throughput Technologies Requiring Computational Analysis

Mid-throughput technologies that identified SNPs utilizing SBE are also desirable as modest multiplexing assays with minimal assay setup costs such as Sequenom MassARRAY platform (Clendenen *et al.*, 2015; Miller *et al.*, 2014). After PCR of the SNP region, a third primer is added that binds one position upstream of the SNP site and the four nucleotide bases linked to terminators are added. The nucleotide at the SNP is extended by an enzyme. The samples genotype is determined by hybridizing extended primers to a universal DNA array and by determining the identity of the extended base by hybridization pattern analysis. This can be used as second-tier applications such as validating hits after genome-wide association studies (GWAS) (Batra *et al.*, 2011; Lose *et al.*, 2012; Lose *et al.*, 2013). SNP microarrays started more than two decades ago and have progressed from low-throughput to the current mid-throughput Affymetrix GeneChip SNP platforms, Illumina Golden Gate Assay or the Infinium Assay of Illumina to study thousands of SNPs simultaneously. In this approach the arrayed DNA is extended at the SNP site in a single extension reaction or the bar-coded oligos are hybridized to a universal array (Cutler *et al.*, 2001; Bumgarner, 2013).

Here for the high-throughput technologies reviewed, initially, we discuss the physical method followed by the computational analysis for the SNP detection.

Sequencing by Ligation (SBL)

SBL approaches comprise the hybridization and ligation of labelled probes of varying lengths and short, known anchor sequences to a DNA strand (Tomkinson *et al.*, 2006). The emission spectra by the fluorophore indicates its complementarity to the probe (Pu *et al.*, 2015). In SBL, the DNA is clonally amplified on a solid surface, the presence of thousands of copies reduces the background noise. The probes encode one or two known bases, enabling complementary binding of the probe to the template. The anchor fragment encodes a sequence complementary to an adapter sequence and initiates ligation. After ligation, the template is imaged to identify the known base or bases in the probe (Landegren *et al.*, 1988). A new cycle starts after removing the anchor-probe complex or removal of the fluorophore by a cleavage event and to restore the ligation site.

Next-generation sequencing (NGS) platforms based on SBL including, SOLiD and Complete Genomics systems utilizes deoxy-nucleotide triphosphates (dNTPs) that are probed multiple times (Valouev *et al.*, 2008). In Complete Genomic's DNA nanoballs' technique, the sequences are obtained by probe-ligation, but the clonal DNA amplification is performed by rolling circle amplification unlike the bead or emulsion amplification. The rolling circle amplification generates long DNA chains with repetitive elements of template bordered by adapters which then assemble into nanoballs that are fixed to a slide and sequenced. Both SOLiD and Complete Genomics systems are termed to have a very high accuracy of ~99.9% and generate both single-end and paired-end sequencing (in which the sequence at both ends of each DNA cluster is recorded) (Drmanac *et al.*, 2010; Liu *et al.*, 2012). Although highly accurate, they still are reported to miss true variants (Wall *et al.*, 2014) and false representation of AT-rich regions (Rieber *et al.*, 2013). For example, SOLiD system display substitution errors and GC-rich under-representation (Harismendy *et al.*, 2009). They also generate very short read lengths (~75 bp for SOLiD and 28–100 for Complete Genomics) limiting their wider application and longer run times.

Polony sequencing is a technique to amplify DNA *in situ* on a thin polyacrylamide film. The amplified DNA are localized in a gel and thus its mobility is restricted to the gel and form the so-called "polonies" for polymerase colonies (Shendure *et al.*, 2005). On a single microscope slide nearly 5 million polonies can be formed. The read length by this technique is up to 13 bases per colony (Zhang *et al.*, 2006) and multiplexing using this technique is also in use that combines polony amplification along with sequence-by-ligation method to sequence up to 14-base tags (Ruegger *et al.*, 2012). The limitation associated with this technique is low throughput and high costs.

Sequencing-by-Synthesis (SBS)

SBS can be classified into cyclic reversible termination (CRT) or as single-nucleotide addition (SNA)

Cyclic reversible termination (CRT)

CRT utilizes terminator molecules similar to Sanger sequencing by blocking the ribose 3'-OH group thus preventing elongation (Seo *et al.*, 2005). To begin amplification, the DNA template need to be primed by a complementary sequence to adapter. This will initiate the binding of DNA polymerase to double stranded DNA (dsDNA). At each cycle, uniquely labelled dNTPs specific to each base are added after which the surface is imaged to identify the type of dNTP incorporated at each cluster (Guo *et al.*, 2008). The blocking group is then removed and a new cycle begins.

One example for this technique is Solexa Genome Analyzer uses a flow cell consisting of an optical transparent slide with 8 lanes of bound oligonucleotide anchors (Voelkerding *et al.*, 2009). Template DNA is sheared into 100 bp lengths and end-paired to generate 5'-phosphorylated blunt ends. The DNA fragments are then passed over complementary oligonucleotides bound to a flowcell and a follow-up solid phase PCR generates clusters of clonal populations from each of the individual flow-cell binding DNA strands. Sequencing is by SBS using fluorescent 'reversible-terminator' dNTPs that allows the sequencing to occur in a synchronous manner (Turcatti *et al.*, 2008). The incorporated nucleotide at each cycle is monitored by a charged couple device (CCD) by exciting fluorophores with laser light, before the removal of the fluorescent moiety and continuation to next step. Earlier Genome Analyzers were only capable of short reads (~35 bases long) but can produce paired-end data. NextSeq and MiniSeq platforms utilize two-colour labelling system and reduce the costs by reducing scanning to two colour channels. However, this results in a higher error rate and underperformance for less diverse samples. MiSeq has a low-throughput but less expensive with faster turnaround and longer read lengths (Balasubramanian, 2011; Quail *et al.*, 2012).

GeneReader (Qiagen) is envisioned for clinical application on cancer gene panels and is well optimized (Darwanto *et al.*, 2017). It's an all-in-one platform from sample preparation to analysis. The NGS platform is coupled with QIAcube for sample preparation. With a long run-time GeneReader is likely to have the same merits and demerits as the MiSeq platform providing a lower cost effective option per gigabase (Gb) sequenced (Mardis, 2017). The standard Genome Analyzer was later taken over by the HiSeq that is capable of a greater read length and depth but needs rigorous optimization and therefore is limited for fewer applications such as whole genome sequencing. Cancer panels (Novogene, USA) for personalized medicine that specifically targets cancer specific utilizing HiSeq for sequencing are currently available. This cancer panel called NovoPM™ is available for both tissues, liquid biopsy, FFPE and circulating DNA and is considered to be cost-effective service for cancer studies.

Single-nucleotide addition (SNA)

SNA relies on a single signal unlike CRT to incorporate dNTPs into an elongating strand. The nucleotides are added to a sequencing reaction to ascertain that only one dNTP is responsible for the signal. This doesn't require blocking of the dNTP as in CRT to prevent elongation. For the homopolymer regions that involves identical dNTPs, a proportional increase in the signal will be observed as the nucleotides get incorporated.

Pyrosequencing is a sequence-by-synthesis method for *de novo* DNA sequencing. The technique is based on the incorporation of nucleotides base by base by converting the production of pyrophosphate into light (Ronaghi *et al.*, 1998). The amount of pyrophosphate is proportional to the light produced (Royo *et al.*, 2007; Royo and Galan, 2009). The read length for pyrosequencing has an upper limit of 400 bases and has a better detection and accuracy compared to the conventional Sanger sequencing. However, the major concern with this technique is determining the number of incorporated nucleotides in homopolymeric regions as the light response is not linear after incorporation of more than 5–6 identical nucleotides. Further, the primers need to be checked for primer-dimer, self-looping and cross-hybridizations (Heather and Chain, 2016). One example utilizing this principle is 454 Pyrosequencer developed by Life Science in 2000. The 454 Pyrosequencer is the first commercial high throughput-next generation sequencing (HT-NGS) platform. This SNA method distributes beads bound to the template into a TiterPlate along with enzyme cocktail (Batra *et al.*, 2014). As a dNTP gets incorporated into a strand, enzymatic cascade occurs liberating a bioluminescence signal. The light is then detected by a CCD camera that records the number of nucleotides incorporated at a particular bead.

The Ion Torrent is the first sequencer without optical sensing (Rothberg *et al.*, 2011). To generate a signal the Ion Torrent detects the H⁺ ions released after each dNTP incorporation. The resultant change in pH is recognised by an integrated ion-sensitive field-effect transistor (ISFET) and a complementary metal-oxide-semiconductor (CMOS). The change in the pH is proportional to the number of nucleotides identified. But this limits the accuracy in detection of the length of homopolymers. The 454 and Ion Torrent systems generate greater read lengths compared to other short-read sequencers with an average read length of 700 and 400 bp, respectively (Goodwin *et al.*, 2016). This offers advantage especially for sequencing repetitive DNA regions or complex DNA. However, insertion and deletion errors dominate for homopolymers although they are compared to be on par compared to other NGS platforms in sequencing non-homopolymers. The 454 sequencers could not compete with the upcoming new technologies in terms of yield or costs (Voelkerding *et al.*, 2010).

Ion Torrent platform offers a wide range of chips and instrument to consumer needs for chips ranging from ~50 megabase (Mb) to 15 Gb with a shorter runtime ~2–7 h, making it the faster than other current platforms (Stahl and Lundeberg, 2012). Some of them are currently used for clinical applications, transcriptome profiling and splice sites detection. The Ion Personal Genome Machine (PGM) and the Ion S5 series are some of the machines currently used for dedicated diagnostic applications

(Roy *et al.*, 2016). The Ion Proton and S5 devices cannot perform paired-end sequencing, thus limiting their application for elucidating long-range genomic or transcriptomic structure.

Long-Read Technologies

Genomic DNA harbors long repetitive elements, copy number alterations and structural variations that makes it highly complex. Short-read paired-end technologies are not sufficient to resolve these complex elements and require technologies that can deliver long-reads for resolution of the long structural features. Currently, there are mainly two types of long-read technologies: single-molecule real-time sequencing and synthetic long-reads

Single molecule real-time long reads

The first single molecule sequencing (SMS) was developed by Stephen Quake *et al.*, and later commercialized by Helicos Biosciences (Pushkarev *et al.*, 2009). In this technique, DNA template is attached to a planar surface, and fluorescent reversible terminator dNTPs are washed over one base at a time, imaged and cleaved before the next base is cycled. This is a slow and expensive technique but was the first sequencing technology of non-amplified DNA, thus avoiding errors and biases (Heather and Chain, 2016).

Currently the widely used long-read technology is the single-molecule real-time (SMRT) sequencing approach by Pacific Biosciences (PacBio). PacBio[®] RSII sequencer uses a flow cell with thousands of picolitre wells – zero-mode waveguides (ZMW). Short-read SBS techniques (Illumina sequencers) bind the DNA and allow polymerase to bind to the template, PacBio anchors the polymerase to the well and allows DNA to travel through the ZMW (Rhoads and Au, 2015; Larkin *et al.*, 2017). SMRT also uses a unique circular template for the polymerase to traverse repeatedly thus allowing the sequencing of DNA multiple times to generate continuous long read (CLR). The polymerase then cleaves the fluorophore bound to the dNTP incorporated. The average length of a CLR is 10–60 kb and depends on the polymerase half-life. The SMRT-sequencing reads are then mapped by tools such as BLASR that allows confident mapping of the reads to their reference sequence.

In 2014, a first consumer prototype of a nanopore sequencer to generate long-reads was released – the MinION, Oxford Nanopore Technologies (ONT). ONT directly sequences a native ssDNA by measuring the changes in the current as the bases are stringed through the nanopore by a molecular motor protein. ONT MinION uses a hairpin library structure, the DNA template and its complement are bound by a hairpin adapter similar to the PacBio circular DNA template (Oikonomopoulos *et al.*, 2016). The raw reads are then split into two “1D” reads (“template” and “complement”) after removing the adapter (Laver *et al.*, 2015). Due to similar data features with PacBio, many researchers have utilized or are testing ONT in applications where PacBio has been applied. Because of the unique nature of ONT technique, as there are 1000 distinct signals, it has a large error rate (~30%) particularly for indel errors. Homopolymer sequencing also remains a challenge for ONT MinION and PacBio. Further the cost per base is higher than Illumina platforms and the per-base error rates are high (5%–15%) (Cornelis *et al.*, 2017). Recently, improvements and algorithms to improve the accuracy are in progress.

Synthetic long-reads

Synthetic approaches generate long-reads by library preparation that barcodes associate fragments to allow assembly computationally of a larger fragment. Large DNA fragments are partitioned into microtiter wells or into an emulsion with few molecules in each partition. The template fragments within individual partition are sheared and barcoded. This allows sequencing on existing short-read instruments, after which the data are split by barcoding and reassembled. By segregating fragments, complicated regions can be isolated allowing for them to be assembled locally. This reduce the breaks (gaps) in the obtained sequence data (Schatz *et al.*, 2010; English *et al.*, 2015). Two popular systems using this technique are the Illumina synthetic long-read sequencing platform and 10X Genomics emulsion-based system.

The Illumina Truseq Long-Read DNA partitions DNA into a microtiter plate and do not require special instrumentation whereas the 10X Genomics emulsion-based system use emulsion to partition DNA and use a microfluidic instrument for pre-sequencing reactions (Mccoy *et al.*, 2014). The DNA required for 10X Genomics is as little as 1 ng (nanogram) and can arbitrarily partition large DNA fragments (~100 kb) into micelles known as ‘GEMs’. Each GEM would contain approximately 0.3x genome copies and a unique barcode. Within each GEM, smaller fragments of DNA are amplified. The reads are aligned and grouped together to form a series of anchored fragments across the original fragment. Grouped reads from each long fragment can be restacked, combining their individual coverage into an overall map. As the Illumina long-read approach relies on the existing instrument, the throughput and error profile are similar to those of the current short-read sequencers (Goodwin *et al.*, 2016). Depending on the method of DNA partition, higher coverage is required, thus is associated also with high costs using the Illumina long-read approach. The 10X Genomics uses less DNA but the partitioning is not very effective and can lead to surplus DNA within a droplet complicating deconvolution. This leads to ambiguity and makes analysis difficult.

Analysis of the SNP Data Generated by the Sequencers

The last few years have seen incredible progress in the development of algorithms and software to make sense of the short reads onto a reference sequence and to identify the differences between the individual and the reference. The complexity of genome

makes it impossible to generate genetic maps that are based on the segregation of genetic variations through pedigrees that provided information about the order of sequences at specific loci and at the chromosomes scale. Most popular SNP callers are focused primarily on the high recovery of SNPs while keeping low false discovery rates.

De novo assembly to the reference genome

The first step in data analysis is alignment of the short sequences obtained from the sequencing methods to the existing reference genome. Alignment starts with indexing, following alignment. The common aligners are Bowtie2 and SOAP3-dp that index reference genome rather than sequenced reads, which is less time consuming as indexing reference needs to be performed only once, while indexing sequence has to be performed for each sample individually (Luo *et al.*, 2013). Some of the indexing methods are suffix/prefix trie, enhanced suffix array, FM-index and hash table. The *suffix/prefix trie* is defined as a data structure representing the set of suffixes of a given string of characters, enabling fast matching of the string (a sequence read) to the reference genome. However for very large data, this method is not efficient and replaced by the enhanced suffix array approach that enables storing of large genome data. FM-index is considered to be better of the first three indexing methods and some popular software tools utilizing this algorithm are Bowtie, SOAP2 and SOAP3 (Chacon *et al.*, 2013). The hash table method is based on the seed-and-extend algorithm. Some of the algorithms in use using the hash table method are BFAST, MAQ, RMAP and SHRiMP (Wu, 2016).

Regardless of the indexing method, the alignment can be performed by many algorithms and the resulting alignment can be gapped or ungapped (Yorukoglu *et al.*, 2016). Alignment gaps are a result of genomic rearrangements, such as insertions/deletions. Allowing gaps in alignment is a preferred option by most alignment software tools. The first alignment tool, SHRiMP was able to perform alignment for single-end sequence and currently most of the algorithms support a paired-end alignment which considers both forward and reverse orders as a pair resulting in a longer piece of sequence and improving quality of alignment.

Post-alignment processing

The most commonly applied post-alignment methods include output file format converting, removing PCR artefacts or creating reports from the alignment process (Mielczarek and Szyda, 2016). These can be carried out using SAMtools package. SAMtools allows reducing the data set size and downstream compatibility with variant callers, such as Unified Genotyper (Genome Analysis Toolkit package) and other software tools (Cornish and Guda, 2015). A simple summary is generated to describe the alignment process (Bowtie2, SOAP2, and MOSAIK) and the description includes the total number of aligned reads, number of properly aligned reads, number of reads aligned only once. Summary statistics helps to assess the overall quality and accuracy of alignment. Removing PCR duplicates can be done by SAMtools rmdup tool (Ebbert *et al.*, 2016).

Pre-variant calling processing

To obtain reliable polymorphic variant calling, additional steps for SNP calling are recommended before the actual variant detection. Some alignment artefacts occur during alignment that may result in mismatching of different bases. These mismatches are most likely to be considered as SNPs (Nielsen *et al.*, 2011). To avoid this, local realignment tools are designed that allows realignment of reads at the site of the artefact to minimize the number of mismatching bases. A large amount of genomic DNA require realignment due to the presence of InDels with respect to the reference genome (Olson *et al.*, 2015). A sequencer may miscalculate the base quality expressed as the Phred score. Genome-analysis-toolkit (GATK) package tools recalibrate base quality scores to more accurate estimates to reduce the mismatches with the reference genome (Mckenna *et al.*, 2010; Maretty *et al.*, 2017). SAMtools provide a score for each base called a base alignment quality (BAQ) score, which is calculated as Phred-scaled probability for a base being misaligned. If a base is sub-optimally aligned to a different reference base, the BAQ score is low. Some programs do not allow pre-SNP calling step, two examples include SOAPsn and Atlas-SNP2 (Yu and Sun, 2013).

SNP calling

Conventionally SNPs were identified by techniques such as microarrays. Today microarrays have tremendously progressed to process about hundreds of thousands of SNPs. Some of the platforms such as Affymetrix, Illumina based on microarray for SNP detection utilize software such as Dynamic Model software (100 K SNPs) that do not require any normalization step (Di *et al.*, 2005), Bayesian Robust Linear Model with Mahalanobis Distance Classifier algorithm for 500 K SNP arrays (Hong *et al.*, 2008) and GenCall algorithm (Teo *et al.*, 2007; Steemers and Gunderson, 2007). Recent NGS techniques have provided new avenues to identify a higher number of variants including the rare SNPs that are important for complex disease phenotypes. However, for a reliable detection of these variants require a high depth of coverage so as to differentiate them from sequencing errors. Multiple algorithms and software tools are currently available for SNP calling. SNP calling may be defined as the process of identifying regions differing from a reference sequence, while genotype calling refers to the determination of genotypes (Nielsen *et al.*, 2011). SNP and genotype callers are based on either heuristic or probabilistic methods.

Heuristic methods call variants are less commonly used than probabilistic methods and are based on multiple information sources associated with the data structure and quality. Example of software using heuristic approach is VarScan2 which is also a statistical test based on the number of reads for each allele (Durtschi *et al.*, 2013). A heuristic approach determines genotype based on thresholds for base quality (minimum 20), coverage (minimum 33), and allele frequency (minimum 0.08). After determining genotype, Fisher's exact test of read counts for each allele is analysed in comparison to the expected distribution based on the sequencing error alone.

Probabilistic method measures statistical uncertainty for called genotypes allowing to monitor the accuracy of genotype calling. Additionally, information regarding allele frequencies, linkage disequilibrium can be included in the analysis. Genotype calling is based on likelihood calculations and adopts Bayes' theorem (Maruki and Lynch, 2014). After realignment and quality score recalibration, the next step is to calculate likelihood for each possible genotype at each base (a homozygote for the reference allele, a homozygote for the minor allele or a heterozygote). In Bayesian framework, the computed likelihood is combined with a previous genotype probability to derive a posterior probability of a genotype (Nielsen *et al.*, 2012; Fumagalli *et al.*, 2013). SAMtools is an example of software including probabilistic approach. SAMtools mpileup collects data stored in input BAM (binary version of the Sequence Alignment Map format) files and computes likelihood of data for each possible genotype. Recently, a study compared thirteen pipelines and popular read aligners against twelve sequence data sets from a single genome. For the SNP calls from Illumina data sets, the BWA-MEM and SAMtools exhibited best performance and Freebayes aligner showed high quality for SNP calls. For SNPs from Ion Proton data set, SAMtools performed best including TVC (Hwang *et al.*, 2015). Thus, researchers must exhibit extreme care when choosing the appropriate algorithms for variant detection and analysis after sequencing.

Conclusion and Prospects

It is difficult to directly compare and suggest the best sequencing system between different platforms. This is because the technique to choose is to be weighed between the costs, coverage and accuracy. Different platforms may require different levels of accuracy to achieve the same level of accuracy and comparisons have to be made either by considering coverage or higher costs to achieve better accuracy. With the increasing research to develop robust sequencing technologies, it is certainly possible in near term that a relatively inexpensive, highly accurate with better coverage sequencer will be achievable that can be used in clinics.

NGS techniques are now becoming a routine part of biological research. These techniques is boosting research into areas which once was thought to be unachievable. Some sequencing-based technologies target single cells that will address many new and longstanding questions. For example, single-cell genomics will help to discover cell lineage relationships and single-cell transcriptomics will succeed in discovering marker-based cell types. In a decade, these technologies may enable high-throughput, multi-dimensional analyses of single cells that will produce comprehensive information of the cell lineage of higher organisms. Such studies will have profound implications to allow revolutionary science including precision medicine based on personalized genome sequencing.

Introduction

The single nucleotide polymorphism (SNP) is a concept in population genetics. It is a polymorphism of a single nucleotide at a specific chromosome position. A SNP locus is a specific chromosome location where the DNA base has two statuses (in most cases) in a population. With the development of high throughput SNP array technology (such as Affymetrix SNP array 6.0) (Nishida *et al.*, 2008) and whole-genome sequencing technology (such as second generation sequencing technology) (Kerstens *et al.*, 2009), the identification of millions (or tens of millions) of SNPs has facilitated the population genetics and medical genetics studies. With this background, the genome-wide association study (GWAS) has been developed and achieved great success (Welter *et al.*, 2014). Thousands of risk loci were successfully identified for complex diseases or phenotypes, such as breast cancer (Garcia-Closas *et al.*, 2013), type 2 diabetes (Cho *et al.*, 2011), and bone mineral density (Rivadeneira *et al.*, 2009). The GWAS focus on the association between single SNP locus and disease/phenotype. However, the single locus does not explain all the genetic risks. Therefore, the haplotype analysis is needed to identify the association between combination types of SNP alleles (multi-loci) and disease/phenotype, where a SNP allele is defined as the base status of one member of homologous chromosomes at a specific chromosome location. There are two alleles for a SNP locus in a population.

In the genome, a group of physically proximate SNPs often nonrandomly associate with each other to form a linkage disequilibrium (LD) block. For two SNP loci, the nonrandom association between SNP alleles at the two SNP loci is called LD. The human LD map for different human populations has been discussed in detail by the International HapMap Project (Altshuler *et al.*, 2010; Frazer *et al.*, 2007) and the 1000 Genomes Project (Abecasis *et al.*, 2010). The LD block may be the smallest heredity unit and is also known as a haplotype block, which is made up of a group of physically proximate SNPs. The SNPs in the LD block are in high LD with each other. A haplotype is defined as a collection of specific SNP alleles on a single chromosome. For k SNPs in a genomic region, if these SNPs are LE of each other, there will be 2^k haplotypes in the population. If the k SNPs are LD of each other, the types of haplotype will be less than 2^k . The genotype at a specific locus is defined as the combination of SNP alleles located on homologous chromosomes. We assume that there are two alleles at the locus: A and a. For an individual, there are three possible genotypes at the locus: AA (homozygote), Aa (heterozygote), and aa (homozygote). The relationships between SNP, allele, LD block, haplotype, and genotype can be found in Fig. 1. For k SNPs in a LD block region, the haplotypes will be less than 2^k . Currently, many genome-wide haplotype association studies have been successfully carried out for identifying the disease/phenotype related genes. For example, by using the genome-wide haplotype association studies strategy, Tregouet *et al.* identified the SLC22A3-LPAL2-LPA gene cluster (chromosome 6q26–q27) as a risk locus for coronary artery disease (Tregouet *et al.*, 2009), Lv *et al.* found that a haplotype TT (rs7090018 and rs2912759) at the gene FGFR2 locus had significant association with acute myeloid leukemia, and Sun *et al.* (2016) identified four oral squamous cell carcinoma related genes, that is, SERPINB9, SERPINE2, GAK, and HSP90B1. The genome-wide haplotype association study is an effective strategy for identifying susceptibility genes of complex diseases/phenotypes.

In general, there are six steps in genome-wide haplotype association study: Data preparation, quality control, LD block identification, haplotype frequency estimation, association test, and multiple testing corrections. Next, we will introduce the six parts in detail.

The Framework of Genome-Wide Haplotype Association Study

The framework of genome-wide haplotype association study includes the following steps (Fig. 2):

Data preparation

Phenotype data: The genome-wide haplotype association study supports both binomial phenotype (case-control) and continuous phenotype (quantitative).

Genotype data: The raw SNP genotypes can be obtained from the SNP array (such as Affymetrix SNP array 6.0) or whole-genome sequencing technology (such as second generation and third generation sequencing technology). SNP array can produce millions of SNPs, and sequencing can produce tens of millions of SNPs.

In general, the phenotype and genotype data can be shown as matrix in Fig. 3. We suppose that there are m samples and n SNPs. Then the genotype data consists of n rows (each row is a SNP) and $k + m$ columns (the first k columns are the basic information of SNPs, such as chr#, position and allele, and the last m columns are the genotypes of SNPs). The phenotype data consists of m rows (each row is a sample) and one column (phenotype).

Quality Control (QC)

In general, there were three commonly used criteria for filtering the raw SNP genotype data: (1) the percentage of individuals successfully genotyped > 75%, (2) Hardy – Weinberg equilibrium ($P > 0.001$), and (3) minor allele frequency (MAF, being the

Fig. 1 The relationships between Single Nucleotide Polymorphism, allele, Linkage Disequilibrium block, haplotype, and genotype.

Fig. 2 The framework of genome-wide haplotype association study.

smaller of the two allele frequencies) $> 1\%$. These QC criteria ensure that the researchers can use high quality, stable, common SNPs (with the MAF > 0.01) to carry out the genome-wide haplotype association study.

Linkage disequilibrium block identification

The nonrandom association of alleles at different SNP loci is usually called LD (Slatkin, 2008). For two SNPs in LD, the frequency of association of their different alleles is higher or lower than random. A LD block (or haplotype block) is made up of a group of physically proximate SNPs that are highly LD to each other. In other words, the LDs between SNPs are higher within blocks and lower between blocks (Wang *et al.*, 2002).

The identification of the LD block is an important step in a genome-wide haplotype association study. There are many methods to identify LD blocks, such as Gabriel's confidence intervals method (Gabriel *et al.*, 2002), four-gamete test (FGT) (Wang *et al.*,

Genotype data

SNP	Chr#	position	Allele	Sample 1	Sample 2	Sample 3	...	Sample m
SNP 1	1	384531	A/T	AA	AA	AT	...	TT
SNP 2	1	396473	A/G	AG	AA	GG	...	AG
SNP 3	1	403251	C/G	CG	CC	CG	...	GG
...	...	...	...	...	...	...	...	...

2002), hidden Markov model (Daly *et al.*, 2001), and the dynamic programming algorithm (Zhang *et al.*, 2002). Although these algorithms can effectively identify haplotype blocks, they are still limited when millions or tens of millions of SNPs are encountered. This is because some blocks are often interrupted by limited computer memory or fixed size windows. To scan the whole-genome smoothly, Xu *et al.* (2016) developed an elastic sliding window method to avoid breaking the real block structure. Firstly, a fixed size sliding window was used to identify the LD blocks in the window. If the last locus in the window is not located in a block, the window was slid to the next locus. Otherwise, if the last locus in the window is located in an identified block, the block is likely to be broken by the border of the window. Then the window size was increased to twice the original fixed window size. The window size can be gradually increased until the last SNP is not in a block. By using this strategy, we can scan the entire genome and identify LD block using very little computer memory. Researchers can identify genome-wide LD blocks by using haplotype analysis software HAPLOTYPE 1.0 (see “Relevant Websites section”).

Haplotype Frequency Estimation

At present, neither SNP chip technology nor the second generation sequencing technology can directly detect haplotypes. This is because the gametic phase is ambiguous when individual genotypes are both heterozygous at two SNP loci. Therefore, some important algorithms, such as expectation-maximization algorithms (EM) (Barrett *et al.*, 2005), Bayesian methods (Scheet and Stephens, 2006), and Markov models (Delaneau *et al.*, 2013), have been developed to phase the haplotype and estimate the haplotype frequency. The phased haplotype can be obtained from the software SHAPEIT (Delaneau *et al.*, 2013) and fastPHASE (Scheet and Stephens, 2006), and the frequency of haplotype can be estimated from the software Haploview (Barrett *et al.*, 2005) and HAPLOTYPE 1.0.

Association Test

For the case-control study, the Pearson’s chi-square test can be used to identify the association between haplotype and phenotype. For a haplotype, we can estimate the haplotype frequency for case and control samples using methods mentioned above.

Then we can calculate the count of the haplotype in the case and control, and construct a fourfold table. The chi-square statistic measures for haplotype (this haplotype versus other haplotypes) and affection status (case versus control) can be found as following:

$$\chi^2 = \sum \frac{(\text{observed} - \text{expected})^2}{\text{expected}}$$

Researchers can also calculated the odd ratio and 95% (confidence interval).

For continuous or quantitative phenotype, researchers can identify the association between haplotype and phenotype using linear regression and variance analysis.

Multiple Testing Corrections

Genome-wide haplotype association study will scan all of the chromosomes, identify the LD blocks, and check the association between each haplotype and phenotype/disease. Therefore, the multiple testing is a challenging issue in genome-wide haplotype association study. Many techniques can be used to correct multiple hypotheses, such as the Bonferroni (Kowalski and Enck, 2010) and Sidak corrections (Guo and Romano, 2007), false discovery rate (Benjamini *et al.*, 2001), and permutation (Chen *et al.*, 2006). The simplest and strictest method of correction is the Bonferroni correction. For each individual hypothesis, researchers can obtain significant results by using a significance level of α/N , where α is the overall significant level and N is the number of hypotheses (the number of haplotypes). If the researchers think the threshold is too strict, they can choose a relatively loose threshold and use a bioinformatics strategy to filter the candidate genes (see Section “Applications”).

Applications

Identifying Complex Disease-Related Haplotype

One of the most important areas of application of the genome-wide haplotype association study is to identify the complex disease-related haplotypes. The disease-related haplotype can be classified into two categories: Risk haplotype and protective haplotype. A haplotype is labeled as risk (or protective) haplotype if the frequency of the haplotype in disease samples is higher (lower) than in control samples. The risk haplotype can increase the risk of disease, and the protective haplotype reduces disease risk.

Mapping Disease-Related Haplotype to Genes

Identifying the disease-related candidate gene is an important application for genome-wide haplotype association studies. The researchers can map the significant haplotypes to genes based on their chromosome location information. The information of start and end sites for all the human genes can be downloaded for the NCBI gene database (see “Relevant Websites section”). The SNP position can be downloaded from the NCBI SNP database (see “Relevant Websites section”). A notable problem is that the genome versions of gene and SNP must be consistent. A gene can be regarded as a candidate gene if the gene shares some chromosome fragment with a risk haplotype.

Analyzing the Gene Functions Using the Bioinformatics Strategy

After obtaining candidate genes, researchers can prioritize the candidate genes based on the correlation (such as sequence similarity and coexpression pattern) with known disease genes. The known disease genes can be obtained from some disease database, such as the Online Mendelian Inheritance (Amberger *et al.*, 2015). The software Endeavor can be used to calculate the similarity between the candidate genes and the known genes from several aspects, such as protein–protein interactions, gene expression, sequence information, text-mining, and gene annotation information (Tranchevent *et al.*, 2008).

Researchers can also analyze the gene functions using the gene annotation database, such as the GO (Gene Ontology) database (Blake and Harris, 2008) and KEGG pathway database (Kyoto Encyclopedia of Genes and Genomes) (Kanehisa and Goto, 2000). Some methods of gene enrichment analysis, such as hypergeometric test and enrichment disequilibrium (Jiang *et al.*, 2012), can be used to identify the disease-related pathways and gene functional categories.

The Haplotype Analysis Software

Here we briefly introduce the most commonly used haplotype analysis software. Using this software, researchers can successfully perform haplotype analysis.

HAPLOTYPE can carry out genome-wide haplotype association study using an elastic sliding window method. The software can be downloaded at the website provided in “Relevant Websites section”.

Haploview is one of the most commonly used haplotype analysis software programs. It supports single SNP and haplotype association tests for limited loci. The software can be downloaded at the website provided in “Relevant Websites section”.

Plink can scan the whole-genome and carry out the genome-wide haplotype association study. The software can be downloaded at the website provided in “Relevant Websites section”.

Shapit can quickly estimate the phase of haplotype. The software can be downloaded at the website provided in “Relevant Websites section”.

An Example

For better understanding the genome-wide haplotype association study, we describe an example. Previously, Wang *et al.* (2015) carried out a genome-wide haplotype association for 33 Chinese prostate cancer patients and 139 normal samples. All the samples

are unrelated individuals. A total of 632,532 SNPs on 22 autosomal chromosomes had passed QC criteria ($MAF > 1\%$, Hardy–Weinberg equilibrium $P > 0.001$, and call ratio $> 75\%$). Then they scanned the whole-genome using a FGT and identified 138,072 LD blocks. For each block, an EM algorithm was used to estimate haplotype frequencies for prostate cancer samples and normal samples. There were total 558,565 haplotypes in the 138,072 LD blocks. For each haplotype, a chi-square test was used to obtain the significant haplotypes. At last, 794 haplotypes were significantly associated with prostate cancer. These significant haplotypes were located in 694 LD blocks. To find the novel prostate cancer related gene, they mapped the significant haplotypes to genes based on physical position and obtained 454 candidate genes. Then Endeavor software was used to prioritize the candidate genes based on the similarity with 13 known prostate cancer genes. In the end, they identified seven novel susceptibility genes. Among these genes, the most significant gene is BLM in chr15. A haplotype GGTACCCCTC (rs2270131, rs2073919, rs11073953, rs12592875, rs16944863, rs2238337, rs414634, rs401549, rs17183344, rs16944884, and rs16944888) on the BLM gene region has significant association with prostate cancer ($P = 2.37E - 11$). The haplotype frequency is 0.16 in prostate cancer samples, whereas it is only 0.0004 in normal samples. The haplotype is a risk haplotype. For other genes, we will not describe them in detail. For more details, please see the research report (Wang *et al.*, 2015).

Discussion

The genome-wide haplotype association study is an important strategy for identifying diseases/traits related haplotypes (chromosome segments) and mapping candidate genes. However, there are still some technical limitations. The main reason is that current SNP detection techniques break the association between physically proximate SNPs. This directly leads to an unknown gametic phase when two SNPs are both heterozygous. Both SNP chip technology and second generation sequencing technology cannot solve this question. With the development of genome sequencing technology (perhaps the fourth or fifth generation sequencing technology), the haplotype will be sequenced directly rather than inferred, and haplotype analysis will become a hot issue.

In some cases, the researchers have only SNP genotype data for disease, and no control data. They can use some public genotype data in the same or similar population as control samples, such as the 1000 Genomes Project.

We will gradually share some learning materials and data on the HAPLOTYPE website provided in “Relevant Websites section”.

Conclusions and Future Directions

Genome-wide haplotype association studies are an important tool in medical genetics studies.

When the haplotype can be directly sequenced, genome-wide haplotype analysis will become a very important analytical tool. In addition, the genome-wide haplotype association study framework will possibly be extended to other omics, such as the epigenome. For DNA methylation, there was also nonrandom association between neighboring methylation loci (we called methylation disequilibrium, MD). A group of methylation status (M: Methylation or U: Unmethylation) on a chromosome can also be defined as a methylation haplotype (meplotype). The genome-wide haplotype association study could be extended to the epigenome-wide meplotype association study. Related concepts can be seen in the framework for population epigenetic study (Zhao *et al.*, 2018). The analysis program for meplotype and single methylation polymorphism (SMP) (Xu *et al.*, 2018) can be found at EWAS website provided in “Relevant Websites section”.

Acknowledgment

We thank Di Liu (Harbin Medical University, China) and Linna Zhao (Harbin Medical University, China) for their contributions to the figures and materials. This work was supported in part by the National Natural Science Foundation of China (Grant No. 91746113). The funder had no role in study design, data collection and analysis, decision to publish, or preparation of the manuscript.

Prediction of Protein-Binding Sites in DNA Sequences

Kenta Nakai, The University of Tokyo, Tokyo, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

In the nucleus of living cells, DNA molecules are specifically bound by a number of proteins to be functional. Of these, the most abundant ones are histones and their related proteins, which are important for organizing nuclear DNA into chromatin and for regulating their structure by epigenetic mechanisms. This topic is described in another article. Here we mainly deal with the binding of transcription factors (TFs) because it is critical in understanding how gene expression is regulated and has been extensively studied. The transcription-factor binding sites (TFBSs) are recognized as *cis*-elements in DNA sequences. Compared with a parallel problem of predicting DNA-binding regions in protein sequences or protein 3D structures, locating TFBSs in DNA sequences can be more difficult because the regions surrounding TFBSs are not necessarily similar between instances. In other words, (global) sequence alignment-based methods are not so effective, though so-called phylogenetic footprinting is effective when evolutionarily orthologous regions are compared (see below). Thus, a specialized field known as the motif-finding (or motif-discovery) problem has been formulated and studied well so far. In this problem, a set of DNA sequences, each of which is likely to contain at least one common TFBS, are given and these TFBSs which are recognized as an over-represented motif, i.e., a short sequence pattern with some statistical significance, are extracted. Typically, the input sequences are the potentially regulatory regions, such as the upstream 1000 bp-regions from the TSSs (transcriptional start sites), of co-expressed genes, i.e., genes which share a similar condition-specific expression and thus are likely to be regulated by a common mechanism, such as by a common transcription factor. As described below, many algorithms have been developed and their performances have been evaluated. More recently, the appearances of the NGS (next generation sequencing) technology, particularly the ChIP-seq (chromatin immunoprecipitation sequencing) technology, which enable to map the binding regions of a specified TF to the entire genome, have changed the situation of this field significantly. For one thing, the scale of the input sequences has been enlarged enormously. For another, a new need of algorithms for locating a TFBS in each ChIP-seq peak has emerged and algorithms specifically tailored for the ChIP-seq data analysis have been developed. In addition, demands for expanding the motif-finding problem to capture the more general architecture of gene regulatory regions have also emerged.

Many review articles have been written in this field. Of these, [Zambelli et al. \(2013\)](#) was written with a similar perspective with this article, though it is not so new. A more recent review by [Liu et al. \(2017\)](#) introduces recent advances, focusing on the algorithms for analysing ChIP-seq data.

How to Represent Motifs and the Problem of False Positives

The typical length of the binding sites of a monomeric TF is around 6 base pairs (bps) but the length of extracted *cis*-elements can become as long as 20 bps because TFs sometimes bind as a homodimer or a heterodimer. The homodimer binding motifs show the so-called palindromic feature and their central regions are sometimes close to random sequence, which can be regarded as a gap region. However, although the length of such 'gap's can even be varied, the length of sought TFBSs is practically assumed to be constant in motif-finding. In other words, variable gaps are not considered for aligning TFBSs in most cases.

Since the binding sequences of a TF are varied more or less, various ways have been used to represent its binding pattern. As described later, the way of how to represent the binding pattern (motif) is tightly related to the algorithms for finding it. Roughly speaking, there are two types of representing motifs: one is character-based and the other is numerical (profile-based).

The former character-based representation is related to the consensus-sequence representation, which shows the most frequent base at each position (in its simplest form). For example, the consensus sequence of the TATA-binding protein is known as 'TATAAT', though most of its known binding instances are not 'TATAAT'. It is well known that the frequency of base appearance at each position is not the same and thus sometimes bases that frequently appear are shown with capital letters while less frequent bases are shown in lower cases, such as 'TATaat'. When the majority of the preference of bases is shared with two bases, they are sometimes shown with parentheses, such as 'TATaa(t/a)'. The IUPAC code for representing degenerate bases is often used ([Table 1](#)). These character-based (or pattern-based) representation is a subset of regular expressions in computer science and is relatively easier to be treated in computers. In motif finding, the binding pattern of a TF is sometimes assumed to be represented as the so-called (l, d) -pattern, where l is the length of the pattern (e.g., 6) and d is the maximum number of allowed mismatches from the consensus (e.g., 3).

On the other hand, in the numeric or profile-based representation, the so-called positional weight matrix (PWM) is the standard (it is often referred as a profile). A PWM is a matrix, such as $\{w_{ij}\}$, $i=1,\dots,4$, $j=1,\dots,l$ for a motif with l -bases. The matrix element w_{ij} shows a score when base i appears at position j in the candidate instance. Typically, the score is proportional to the log-odds, which is the logarithm of the frequency of base i at position j in the set of known binding sequences for the TF divided by the background frequency of base i (for the base of the logarithm, 10 or 2 are often used). For each candidate binding site, the score at each position j is summed over the l positions, giving the score for the candidate. If this summed score exceeds a certain

Table 1 IUPAC codes for nucleotides

<i>Code</i>	<i>Base</i>
A	Adenine
C	Cytosine
G	Guanine
T (or U)	Thymine (or Uracil)
R	A or G
Y	C or T
S	G or C
W	A or T
K	G or T
M	A or C
B	C or G or T
O	A or G or T
H	A or C or T
V	A or C or G
N	Any base

threshold parameter, the candidate is predicted to be one of the binding sites. Note that this method adds the logarithms of base frequency; this means that it essentially calculates the probability of observing motifs assuming that the base appearance at each position is independent each other. Practically, the observed frequency of base i can become 0 just because the size of the known set is not large. In such a case, candidates containing such a position will never be predicted to be positive. To avoid this, a small number of artificial occurrence is added to all the matrix elements. These values are called pseudo-counts. According to a study based on simulated data, a value 0.8 was recommended for practical uses (Nishida *et al.*, 2009).

Obviously, the PWM representation contains more information than the (l, d) -representation. In fact, the predicted sites with higher scores are not only more likely to be the true binding sites but also more likely that the TF binds more strongly. Nevertheless, both of these representations suffer from the problem of too many false positives. Namely, in both representations, the binding motif tends to match to too many positions in the genome, many of which are not the true binding sites. In this sense, the matrices stored in public transcription factor databases, such as JASPAR and TRANSFAC, are useful but should be used carefully. Indeed, our fundamental assumption that the short sequence motif is the determinant of specificity for any transcription factor is not accurate at least *in vivo*; exactly the same sequences can be bound at one site while unbound at another. Then, what kind of information should we add? We still do not have accurate answer; it is unlikely that the inherent assumption of positional independence in the PWM representation is the main reason because the incorporation of inter-position dependency does not seem to solve the problem (Zhang and Marr, 1993), though there are a few recent reports that the use of more flexible frameworks (e.g., HMM or deep learning) in motif representation improved the performance (Mathelier and Wasserman, 2013; Alipanahi *et al.*, 2015). Perhaps, the surrounding region with a relatively short range (say, $+/- 10$ bp) does not carry enough information. It is widely believed that the chromatin structure around the (relatively long-range) region is the key. Namely, if the surrounding chromatin is tightly packed and in an inactive state, the sites within it will not be bound but if it is in an open and active state, the sites within it will be more likely to be bound, though detailed confirmation has not been reported as far as the author notice. In this sense, phylogenetic conservation analyses of ChIP-seq data are useful to know what is happening. As an example, Schmidt *et al.* (2010) compared the binding profiles of CEBPA to the region around the PCK1 gene in the liver between five animals. There was a clear peak which is conserved between all five species at the 5' position of the gene but, interestingly, there was also a unique upstream peak which is human-specific, for example. It is not known whether this peak shows an evolutionary acquisition of a new functional element or just shows a randomly appeared, non-functional binding site. Thus, we should mind that even ChIP peaks may not show functional sites and that evolutionary conservation is an effective information to detect functionally important peaks (though not all functional sites are necessary to be conserved).

Algorithms of Motif Finding

In the motif-finding problem, the length of the motif sought is usually given as an input parameter. Each of the input sequence is often assumed to contain (at least) one target binding site (i.e., an instance) but practically, it would be all right, of course, if some of the input sequences do not contain target sites. Based on the representation methods for DNA motifs, the algorithms for motif finding are roughly-divided into two categories: the character-string (or word)-based methods and the numeric profile-based methods. Although there have been more preceding attempts based on word-based approach, a pioneering work which formalized the problem is done in Hertz *et al.* (1990), where they proposed a way to find a kind of PWM which is formed by the instances of input sequences and gives the highest sum of scores intuitively (the method thus belongs to the profile-based category and the improved algorithm is later released as CONSENSUS). Then, two classical algorithms, MEME (Bailey and Elkan, 1994) and Gibbs sampler (Lawrence *et al.*, 1993), which use the Expectation Maximization algorithm and the Gibbs

sampling algorithm, respectively, for optimizing the PWM, appeared. The basic idea of Gibbs sampler is first to randomly locate the instance position for each input sequence and make a PWM from them except one of them; then, the PWM is used to scan the excluded sequence; if another position gives higher score than the original instance. The instance of the sequence is updated with the probability determined by their score difference. Iterating this procedure many times, the PWM will happen to include target instances partially and will start to work efficiently to find the target instances in the remainder of sequences. Finally, the PWM will converge to the optimum one. A boom in this field had come after MEME and a number of algorithms have been developed. Practically, it is recommended to apply a motif finding algorithm with various parameter values and confirm these results by eyes. It would be even desirable to compare the results of multiple algorithms to confirm the stability of the extracted motifs (though there is no guarantee that frequently extracted motifs are more reliable). A tool has been released for helping such procedures (Okumura *et al.*, 2007).

As described above, in the character-string-based approach, the problem is formalized to efficiently enumerate motifs in the form of the (l, d) pattern (Pevzner and Sze, 2000). This formalism is appealing to researchers with the background of computer science and many techniques have been applied to reduce its computational cost. One successful example of this approach is Weeder (Pavesi *et al.*, 2001), which is proposed as a method to detect motifs with unknown length. In 2005, a relatively systematic evaluation of the performance of available algorithms was published, using various benchmark data (Tompkins *et al.*, 2005). Although there was not a single excellent algorithm for all purposes, the performance of Weeder was impressive.

However, with the appearance of the NGS (next generation sequencing) technology, including the ChIP-seq method, the situation has been changed. First, as noted above, more specialized software for the analysis of ChIP-seq data is required. Second and more importantly, the size of the input sequences has been enlarged enormously; for those large inputs, traditional software such as MEME and Weeder are not practical. Third, because the genome sequences of so many organisms have become available, comparison of orthologous regions between evolutionarily close organisms has become easier. Since the topic of phylogenetic footprinting is treated in another article, we do not describe about it further but just cite one pioneering work, which is even earlier than the establishment of the motif finding problem (Tagle *et al.*, 1988) as well as one recent progress (Liu *et al.*, 2016) in the field. Perhaps, the most popular tool for ChIP-seq motif finding is DREME by the author of MEME (Bailey, 2011). DREME belongs to the string (word)-based category and exhaustively finds top 100 words (of length l) which appear most significantly in the positive data compared with the negative data. Then, the top words are merged between similar ones to allow wild-card representation of a mismatch. DREME is also used in the MEME-ChIP web server, which integrates the two types of motif-finding algorithms, MEME and DREME (Machanick and Bailey, 2011), and it is included in a large collection of MEME-related tools, the MEME Suite (Bailey *et al.*, 2015; Fig. 1). The peak-motif tool in the RSAT (Regulatory Sequence Analysis Tools) web server, which is also well-known, belongs to the string-based class but the found motifs are compiled to the form of PWM (Thomas-Chollier *et al.*, 2012). As a pioneering example of numeric matrix-based approach for ChIP-seq peak detection, ChIPMunk, which is an iterative algorithm combining greedy optimization with bootstrapping, is famous (Kulakovskiy *et al.*, 2010). ChIPMunk has been used to construct a comprehensive collection of TF specificity of human and mouse TFs (HOCOMOCO; Kulakovskiy *et al.*, 2018). Another recent algorithm, DeepBind, employs a more general way of representing motifs than PWM and uses the deep learning algorithm, which is known to be quite powerful in various applications (Alipanahi *et al.*, 2015). So far, systematic benchmarking attempts for ChIP-seq motif finders have not been reported well (but see Wilbanks and Facciotti, 2010), probably because of the difficulty in setting correct binding motifs except trivial cases. However, it would be true that, generally speaking, more recently released algorithms are more likely to be better in their performance/speed and that the combined use of algorithms based on different principles are also recommended (for reviews, see Tran and Huang, 2014; Liu *et al.*, 2017, for example).

Variations of the Theme

One way to improve the sensitivity of motif detection is to improve the quality of background sequences, which are not random at all. For example, in the human genome, the frequency of the CpG dinucleotide is significantly fewer and many short repetitive sequence patterns exist. Markov-chain models have been used to capture these features. But there are also needs for more specific discriminative motif finding, where only motifs that significantly occur frequently in the positive dataset rather than the negative dataset are reported. For example, to extract motifs that are responsible for muscle-specific gene expression, ubiquitous signals, such as the TATA box, should not be extracted. Although the use of negative data has been attempted since very early years, the problem of discriminative motif finding can be a specific field to be explored (Redhead and Bailey, 2007; Huggins *et al.*, 2011). The need may have become even more important for the analysis of condition-specific changes of ChIP-seq peaks. And related to this, there is also a great need to extract a set of multiple non-redundant motifs that co-occur in a set of regulatory regions of co-expressed genes and this problem is regarded as the cofactor motif finding. Note that even ordinary motif finders can detect multiple motifs independently. For example, a rather simple algorithm, such as DREME, has been shown to be effective in finding cofactor motifs (Bailey, 2011). Of course, there have been algorithms which can detect co-occurring motifs simultaneously, such as SIOMICS (Ding *et al.*, 2015). This kind of approaches is also related to attempts to characterize the architecture (way of the placement of multiple TFBSs) in the upstream region of co-expressed genes. Some pioneering works were performed by Fickett and Wasserman (2000). Vandenberg and Nakai (2010) tried to systematically extract a set of rules on the combination and their relative placement of *de novo* motifs that can be used to distinguish a set of certain tissue-specific genes from the others. A similar approach was attempted to characterize the structure of *cis* regulatory modules that direct the

Fig. 1 The MEME Suite (<http://meme-suite.org/>).

developmental stage-specific expression of genes in *Drosophila* (Lopez *et al.*, 2017). With the advance of NGS technologies, such as the single-cell transcriptomics, this field should become more flourishing. An important remaining problem to be explored is to find motifs in enhancer regions. In spite of several large-scale experimental and computational studies, it is still a mystery on how transcription factors contribute to specify the enhancer activity (Kheradpour *et al.*, 2013). Systematic attempts to accumulate ChIP-seq and related data in several organisms, such as ENCODE, will offer a powerful foundation in the field (ENCODE Project Consortium, 2012). And future understanding on how the regulatory information is encoded in DNA would be undoubtedly useful in characterizing the relative importance of mutations/variations found in the non-coding regions of our genome, for example.

Concluding Remarks

Looking at the pace of publications in the field of motif-finding, this field has become to be regarded as a maturing field. The performance of the relevant software, however, is still not satisfactory at all. Especially, the problem of high false-positive rate must be overcome. As mentioned above, one important factor to be considered should be the chromatin states, which are closely related to the DNA looping structure, such as the TAD (topologically-associated domains; [Dixon *et al.*, 2016](#)). The chromatin states are predicted from a set of histone mark information, obtained by ChIP-seq. The DNA looping structure is also estimated with NGS-based technology, such as the Hi-C technology (reviewed in [Han *et al.* \(2018\)](#)). With the incorporation of such new advances, this field should experience another new boost in the near future.

Genome-Wide Scanning of Gene Expression

Sung-J Park, The University of Tokyo, Tokyo, Japan

© 2019 Elsevier Inc. All rights reserved.

Introduction

Identifying genetic and epigenetic factors that impact molecular interplay and disease development is a high priority issue in the field of biological and medical sciences. As a solution to this issue, profiling of gene expression with microarray-based technologies has widely been adopted (Hoheisel, 2006). More recently, thanks to the improvement of next-generation sequencing (NGS) technologies, RNA sequencing (RNA-seq) has emerged as a new routine tool for the transcriptome profiling (Wang *et al.*, 2009). Beyond quantifying RNA population, RNA-seq facilitates to discover genome-wide alternative splicing isoforms, transcriptional start sites, epigenetic modifications, and allele specific transcripts. Currently, RNA-seq is gaining more popularity with growing demand of genome assays from communities.

It is often the case that billions of digital RNA fragments produced by NGS machines are computationally processed and statistically tested. Furthermore, to understand functional meaning of gene expression, incorporating multi-omics data that are rapidly increasing in quantity became inevitable. Thus, along with a well-designed experiment setting, successful transcriptome studies require to leverage bioinformatics and to carry out a pipeline that makes studies repeatable and transparent. In this regard, extensive community-wide efforts have been made to guide the effective usage of bioinformatics resources through developing online systems (Henry *et al.*, 2014; Cochrane *et al.*, 2016; Sloan *et al.*, 2016) and conducting benchmarks (Teng *et al.*, 2016; Williams *et al.*, 2016; Yan *et al.*, 2017). However, we frequently remain uncertain which background assumptions, statistical thresholds, or bioinformatics tools are appropriate to individual purposes (Fig. 1).

Herein, after succinctly briefing on the trends in NGS technology, we summarize recent progresses in scanning of genome-wide gene expression and in profiling of its functional importance. We focus on computational and statistical issues for filtering, mapping, quantifying, and annotating the RNA-seq outcomes. To help readers finding new opportunities and challenges, we provide a series of references that expedites understanding of each issue in detail. In addition, this article exemplifies a practical way of gene expression profiling with public data of spermatogenesis (Fig. 2(A)), which strives to avoid profound discussions on the germ cell development reviewed in excellent references (Bettegowda and Wilkinson, 2010; Saitou *et al.*, 2012; Bohacek and Mansuy, 2015; Ernst *et al.*, 2017).

Although we limit our scope of this review to transcriptome analysis, readers can also find attractive themes for processing of multi-omics data that gives a new multifaceted window to the identification of key factors. We expect that transcriptome atlases established by genome-wide scanning of gene expression provide fundamental resource to the extensive genomic studies that require the incorporation of large-scale heterogeneous datasets.

Genomic-Scale Transcriptome Profiling

Applications of High-Throughput Sequencing

The advent of massive parallel sequencing technology has led a new era of genome analysis, which can rapidly produce readouts of billions of DNA and RNA molecules. Since Sanger's success in sequencing a complete genome of virus (Sanger *et al.*, 1977), through a series of technical innovations (Mardis, 2013; Reuter *et al.*, 2015; Park *et al.*, 2016; Shendure *et al.*, 2017), the high-throughput sequencing also known as next-generation sequencing (NGS) is gaining more popularity with growing demand from academic and clinical communities (Koboldt *et al.*, 2013). Indeed, various consortium-based sequencing projects are ongoing towards specific goals (Table 1). They continuously manage the outcomes as public databases that provide new opportunities to unveil biological enigma.

The rapid progress in NGS technology has placed diverse features in commercialized machines (Loman *et al.*, 2012; Reuter *et al.*, 2015; Shendure *et al.*, 2017). For instance, Illumina platforms coupled with advanced experiment protocols, such as immunoprecipitation and enzyme reaction, produce relatively short genomic fragments (i.e., reads). On the other hand, synthetic long-read technologies, such as PacBio (Nakano *et al.*, 2017) and Oxford Nanopore Technologies (Loman and Watson, 2015), have emerged as a recent innovation of NGS technology. These NGS platforms often show trade-off features between pros and cons in throughput, cost per run, and signal-to-noise ratio (Mardis, 2013; Ross *et al.*, 2013; Reuter *et al.*, 2015). Thus, attention

Table 1 Example of consortium-based sequencing projects

<i>Consortium</i>	<i>Purpose</i>	<i>NGS type</i>	<i>Reference (PMID)</i>	<i>Website</i>
Cell Lines Project, Catalog of Somatic Mutations in Cancer (COSMIC)	Identifying genetic abnormalities from over 1000 human immortal cell lines	WES (Whole exome sequencing)	27727438	http://cancer.sanger.ac.uk/
Exome Aggregation (ExAC)	Cataloging human genetic diversity by high-quality exome sequencing data	WES	27535533	http://exac.broadinstitute.org/
Genetic European Variation in Health and Disease (GEUVADIS)	Understanding human transcriptome variation associated with disease-related genetic variation	RNA-seq	24037378	http://www.geuvadis.org/
Genotype-Tissue Expression (GTEx)	Characterizing human gene expression and regulation and its relationship to genetic variation	WGS (Whole genome sequencing), WES, RNA-seq	29022597	https://www.gtexportal.org/home/
International Wheat Genome Sequencing Consortium (IWGSC)	Comprehensive assembly and understanding of genetic features of bread wheat	WGS	25035484	https://www.wheatgenome.org/
Non-Human Primate Reference Transcriptome Resource (NHPRTR)	Cataloging transcriptome landscapes of over 20 tissues in non-human 14 species	RNA-seq	25392405	http://nhprtr.org/
The functional annotation of the mammalian genome 5 (FANTOM5)	Characterizing mammalian promoter features and regulatory elements	CASE-seq, RNA-seq	24670764	http://fantom.gsc.riken.jp/5/
4D Nucleosome Network	Characterizing four-dimensional nuclear architecture and its role in gene expression and cellular function	Hi-C, ATAC-seq, Repli-seq	28905911	https://data.4dnucleome.org/

needs to be paid to the choice of NGS platforms for maximizing the impact on genome sequencing projects, even though it is no doubt that their pervasive utilization will widely spread in communities.

The short-read technologies are frequently used to interrogate broad genome profiling; that is, polymorphism analysis by whole-genome and whole-exome sequencing (Lam *et al.*, 2012; Sudmant *et al.*, 2015), profiling of transcription factor (TF) occupancy (Park, 2009; Kidder *et al.*, 2011), profiling of genomic-scale transcriptome (Wang *et al.*, 2009). The NGS applications can also capture epigenetic variabilities, including DNA and RNA modifications (Laird, 2010; Frye *et al.*, 2016), chromatin accessibility (Buenrostro *et al.*, 2013), and chromosome 3D organization (Paulsen *et al.*, 2014; Ay and Noble, 2015). Although computationally intense, the long-read technologies demonstrate prominent performances in analyzing highly intricate genetic features (Sahraeian *et al.*, 2017); e.g., assembly of high-complex genome regions (McCoy *et al.*, 2014; Li *et al.*, 2015), detection of structural variations (Chaisson *et al.*, 2015), and identification of gene isoforms (Cho *et al.*, 2014; Xu *et al.*, 2015; Weirather *et al.*, 2017).

Profiling Transcriptome Landscape by RNA Sequencing

As a standard application of NGS, RNA sequencing (RNA-seq) enables the broad investigation of protein coding and non-coding transcripts on genomic scales. In this regard, microarray-based technology has been widely used (Hoheisel, 2006; Shi *et al.*, 2006), and is continuously improving its performance in (dis)concordant with RNA-seq outcomes (Marioni *et al.*, 2008; Wang *et al.*, 2014; Nazarov

et al., 2017). Although we expect synergistic and complementary effects of these two assays, RNA-seq offers comprehensive catalog of diverse RNA species, and depicts their transcriptomic and epitranscriptomic landscapes (Wang *et al.*, 2009; Ozsolak and Milos, 2011a; Helm and Motorin, 2017). In fact, recent large-scale RNA-seq projects have revealed remarkable biological characteristics, which includes pervasive transcriptomic feature (Djebali *et al.*, 2012), ingenious promoter usage (Yamashita *et al.*, 2011; Forrest *et al.*, 2014), disease-related transcripts (Weinstein *et al.*, 2013), and dynamic transcriptome waves (Park *et al.*, 2013).

In general, RNA-seq experiments first convert target RNAs into cDNAs that are further amplified. Then, they sequence the amplicons as reads that are computationally mapped on a reference genome. Consequently, the total number of reads mapped to single gene gives the degree of its expression. Of note, various alternative protocols have been developed, such as cDNA-conversion-free RNA-seq (Ozsolak and Milos, 2011b) and amplification-free RNA-seq (Mamanova *et al.*, 2010; Loman and Watson, 2015). Conventionally, RNAs are extracted from bulk cells by considering the cell homogeneity (Park *et al.*, 2013), giving averaged gene expression. Recently, RNA extraction from single cell has emerged (i.e., scRNA-seq) to address key biological issues (Tang *et al.*, 2009; Wang and Navin, 2015) including heterogeneous cell responses that are markedly observed in cancer diseases (Kim *et al.*, 2015), stem cells (Wen and Tang, 2016), and immune systems (Kadoki *et al.*, 2017; Papalexi and Satija, 2018).

Prior to the establishment of transcriptome profiles, researchers have to correct sequencing biases and errors that may occur due to the intrinsic feature of NGS applications (Li *et al.*, 2014; SeqC_MaQC-II Consortium, 2014). To do so, guidelines suggested by the community emphasize many technical issues, such as the importance of multiple biological and technical replicates (Schurch *et al.*, 2016; Merino *et al.*, 2017), the impact of library preparation methods (Parekh *et al.*, 2016), the influence of reference genomes and annotations on downstream interpretation (Hardwick *et al.*, 2017), and the prevention of microbial contaminations (Strong *et al.*, 2014; Olarerin-George and Hogenesch, 2015). Although some issues appear to be highly complex, bioinformatics tools will greatly help the error detection and correction through practical computation and mathematics (Greenfield *et al.*, 2014; Finotello and Di Camillo, 2015; Conesa *et al.*, 2016; Pimentel *et al.*, 2017). One can find a list of related bioinformatics software from the web site of OMIC Tools (Henry *et al.*, 2014).

Bioinformatics for Transcriptome Analysis

Once genomic fragments were determined as reads, bioinformatics further analyzes these digital outcomes for answering biological questions. Thus, along with a well-designed experiment setting, successful NGS studies require to leverage bioinformatics tools and to carry out a pipeline that makes researches repeatable and transparent (Conesa *et al.*, 2016; Kulkarni and Frommolt, 2017). In RNA-seq experiments, the components of a typical pipeline consist of read quality control, mapping to a reference genome, and expression quantification.

The quality control (QC) of reads trims and discards erroneous bases. Since ambiguous base calling leads to misalignments and therefore misinterpretation, the base-call error probability defined as Phred score (Ewing and Green, 1998) is indispensable information. Even if reads include high-quality bases, some of the bases are potentially adapter-origin. For dealing with this issue, many solutions have been proposed; in particular, FastQC (see “Relevant Websites section”), Prinseq (Schmieder and Edwards, 2011), Cutadapt (see “Relevant Websites section”), FASTX-Toolkit (see “Relevant Websites section”), and Trimmomatic (Bolger *et al.*, 2014). Importantly, it should be known that the QC process affects gene expression profile (Williams *et al.*, 2016), which indicates the necessity of scrupulous care.

Spliced mapping tools (Dobin *et al.*, 2013; Kim *et al.*, 2013; Pertea *et al.*, 2016) align RNA-seq reads to a reference genome that includes gene annotations (e.g., exon-exon junctions). This reference-guided approach is helpful to minimize algorithmic biases associated with particular tools. The tools are also applicable to reconstructing transcripts without any reference annotations. This *de novo* transcriptome assembly is a powerful approach for detecting unknown transcripts as well as for novel organisms (Grabherr *et al.*, 2011; Xie *et al.*, 2014). It should be noted that some portion of total sequenced reads are not mapped to the reference genome but mapped to its alternate assemblies and contigs that have been unplaced in building the reference genome. For instance, Fig. 2(A) exhibits 66.8%–91.6% mappability with the mouse reference genome GRCm38 (2647.54 Mb in size), and shows that 8.1%–24.1% in total reads are mappable to the alternate sequences of GRCm38 downloadable from public databases (8373.72 Mb in size). This underlines the possibility that the reference-guided approach misses one fourth of transcriptome in a worse case, which requires further investigation on its impact.

To quantify gene- or transcript-level expression, the mapped reads are rigorously addressed in terms of read depth and transcript-width coverage. Since the short reads are results from random cutting of RNA molecules, the transcript length and total number of sequenced reads affect the quantification (Conesa *et al.*, 2016). Therefore, normalization within a sample as well as among samples is an essential process that is still actively developed (Mortazavi *et al.*, 2008; Trapnell *et al.*, 2010; Risso *et al.*, 2014; Teng *et al.*, 2016; Jin *et al.*, 2017). The units frequently used in the normalization include FPKM (Fragments Per Kilobase of transcript per Million mapped reads), RPKM (Reads Per Kilobase of transcript per Million mapped reads), TPM (Transcripts Per Million), CPM (Counts-Per-Million), and PPM (Parts Per Million).

For example, HISAT2-Cufflinks2 pipeline (Trapnell *et al.*, 2012; Pertea *et al.*, 2016) first merges all the transcript assemblies coming from multiple replicates of each sample. Then, Cufflinks package counts mapped reads incorporated with the merged assembly, and scales the counts using the median of the geometric means of fragment counts across all samples (Anders and Huber, 2010). In the case of Fig. 2, the total read number of each replicate was adjusted to 1.78725×10^7 by a formula with each scale factor (Fig. 2(B)), which yields the broad dynamic range of gene expression value FPKMs that makes easy to detect differentially expressed genes (Fig. 2(C)).

Functional Profiling With Transcriptome Data

Identifying Differentially Expressed Genes

To scan biologically relevant genes, further investigation with a transcriptome profile may focus on categorizing gene expression changes. In this regard, the identification of differentially expressed genes (DEGs) between two samples is one of the most frequently used approaches, which employs a statistical model for the distributional approximation among biological replicates of the two samples. The statistical models, such as Poisson distribution, negative binomial distribution, Bayesian, and bootstrapping, have been embedded in a large number of tools (Marioni *et al.*, 2008; Hardcastle and Kelly, 2010; Robinson *et al.*, 2010; Wang *et al.*, 2010; Bray *et al.*, 2016; Dong *et al.*, 2016; Pimentel *et al.*, 2017). On the other hand, recent systematic benchmarks for these tools indicate that hidden factors underlying statistical assumption affect reproducibility and false discovery rate (FDR) in the DEG detection (Schurch *et al.*, 2016; Teng *et al.*, 2016; Jin *et al.*, 2017; Merino *et al.*, 2017; Pimentel *et al.*, 2017).

As an example, Fig. 2(D) shows the number of DEGs in consecutive stages, and Fig. 2(E) shows a subset of the DEGs excluding genes expressed (> 3.0 FPKM) either in MEF or Sertoli cells, which indicates sperm-specific transcriptomic bursts at the mitotic and meiotic stage SG, SC, and SD (Margolin *et al.*, 2014). Cuffdiff (Trapnell *et al.*, 2012) defined these DEGs using two empirical thresholds; FPKM fold-change (FC) and Q-value. The Q-value denotes FDR in which Benjamini-Hochberg correction adjusted P-value of two-group t-test (Storey and Tibshirani, 2003). Volcano plot visualizing the effect of two thresholds is typically used to identify the most meaningful DEGs (Fig. 2(F) and (G)).

Grouping Gene Expression Patterns

Given a transcriptome profile from multiple cells and/or multiple time points, genes and transcripts often exhibit dynamic expression waves that DEGs can hardly explain. To decompose the profile into expression waves, bioinformatics of so-called spatio-temporal gene expression analysis employs various computational algorithms including principal component analysis, matrix decomposition, t-distributed stochastic neighbor embedding (t-SNE) analysis, and network analysis (Domazet-Lošo and Tautz, 2010; Shapiro *et al.*, 2013; Hashimshony *et al.*, 2015; Chou *et al.*, 2016; van Dam *et al.*, 2017).

As a straightforward method, clustering analyses clearly show gene groups with similar expression patterns (Eisen *et al.*, 1998; Oyelade *et al.*, 2016). For instance, to prepare a clustering heatmap (Fig. 3(A)), FPKMs shown in Fig. 2(C) formatted a matrix Genes $\times$ Stages, and the matrix was converted into relative values by quantile normalization and matrix mean centering. Then, a clustering method grouped the matrix rows using Euclidian distance metric and hierarchical average linkage method (Fig. 3(A)). The method also grouped the matrix columns using Pearson's correlation coefficient, showing (dis)similarity of gene expression patterns among the developmental stages (Fig. 3(B)). As a result, one can trace gene clusters that may share biological functions (Fig. 3(C)). Of note, the clustering considered relative values without FPKM trimming and cutoff. Thus, absolute FPKMs of genes in a cluster might vary in degree even if their expression dynamics are highly similar. For example, Cluster 2 exhibits repressive FPKM distribution compared to Cluster 9 (Fig. 3(C)); 51.6% of genes in Cluster 2 (1503/2914) are < 3.0 FPKM at E14.5. Consequently, expression filtering with a threshold may affect further interpretation.

Annotating Functional Importance of Genes

In order to reveal functional meaning of key genes, bioinformatics tools search functional genome databases with a gene list, and subsequently perform statistical tests to infer whether any biological annotations are enriched in the genes compared to a background gene set. The approaches include Gene Set Enrichment Analysis (GSEA), Gene Ontology (GO) enrichment analysis, and pathway signature analysis (Subramanian *et al.*, 2005; Huang da *et al.*, 2009; Hung *et al.*, 2012; Yu *et al.*, 2016; Kanehisa *et al.*, 2017). Remarkably, all of the methods exploit knowledge repositories that have become indispensable for interpreting biological functions. Therefore, opening and sharing functional annotations in a standardized data format are increasingly important.

A difficult consideration in the enrichment analysis is to reduce FDR by controlling a balance between false positives (type I error, incorrectly inferring "enriched" from truly "not enriched" results) and false negatives (type II error, incorrectly inferring "not enriched" from truly "enriched" results) (Storey and Tibshirani, 2003; Curtis *et al.*, 2005). Also, since repeat enrichment tests for a gene set with different biological terms increase the change of observing false positives, researchers might adjust raw P-values by such as Benjamini-Hochberg procedure and Bonferroni correction (Storey and Tibshirani, 2003; Schwartzman and Lin, 2011). However, the multiplicity correction needs an attention due to leading to contradictory results with higher type II error rate, which is still under argument along with the issue of what P-value threshold is appropriate to enrichment decisions (Perneger, 1998; Sterne and Davey Smith, 2001).

In Fig. 3(A), among 16 clusters that the number of member genes is > 100 , ten clusters showed GO terms enriched by the tool of GOC (Gene Ontology Consortium, 2015), which indicates the involvement of common or unique biological processes (Fig. 3(D)). This enrichment analysis conducted Bonferroni correction, and picked up GO terms only if < 0.001 FDR. When other options for statistical test were used, the results presented broader GO term enrichment including the result in Fig. 3(D). Interestingly, genes in Cluster 8 transiently up-regulated at SG (Spermatogonia) are significantly involved in cell differentiation processes; at this stage, SG undergo mitotic proliferation and maturation (Ernst *et al.*, 2017). Also, Cluster 2 showing transient gene expression at E14.5 is

Fig. 3 An example of clustering analysis of transcriptome complexity. (A) Hierarchical clustering retrieving 16 clusters in which the number of genes in a cluster is over 100; among the clusters, 10 clusters showed significant GO term enrichment. (B) Dendrogram showing (dis)similarity of gene expression patterns among samples based on the distance of Pearson's correlation coefficient. (C) Examples of relative and absolute expression patterns; red line stands for the mean of relative FPKMs, and boxplot shows corresponding absolute FPKMs. (D) Result of GO term (biological process) enrichment analysis using Q-value of Bonferroni correction (< 0.001).

involved in olfactory sensory activity. Indeed, over 500 olfactory receptors (ORs) are located in this cluster, and the genes without weakly expressed (< 3.0 FPKM) still exhibited the enrichment of term “sensory perception of smell” (GO:0007608); FDR = 4.38×10^{-10} . Although ORs play importance roles in spermatogenesis (Fukuda and Touhara, 2006), unlike ORs highly expressed in Cluster 6, this activity might be related to epigenetic reprogramming; at E14.5 and E15.5, DNA methylation is globally erased and rapidly re-acquired (Bohacek and Mansuy, 2015).

Integrating Transcriptome With Multi-Omics Data

As ENCODE has illustrated (Djebali *et al.*, 2012), complex intra- and inter-molecular crosstalk is observed among regulatory elements, which indicates the necessity of projection of other omics data (e.g., epigenomics, proteomics, and metabolomics) onto transcriptome data. Extensive efforts have therefore been made for emerging multi-omics importance that can be manifested by various NGS assays, and have expedited the understanding of a wide range of biological phenomena (Hasin *et al.*, 2017; Li *et al.*, 2018; Lowe *et al.*, 2017). For example, ICGC and GTEx consortia have released multi-omics datasets in unprecedented scale, facilitating studies in the association of molecular signatures and phenotypes across large number of different cancer types and tissues (International Cancer Genome Consortium *et al.*, 2010; GTEx Consortium, 2017; Li *et al.*, 2017).

We expect that biases led from the heterogeneous datasets introduce highly confounding results with low reproducibility. Therefore, to integrate the multi-omics data by reducing unfavorable effects is a hot topic in bioinformatics, and a line of researches has proposed advanced computational algorithms (Gomez-Cabrero *et al.*, 2014; Huang *et al.*, 2017). These include matrix factorization (Zhang *et al.*, 2012), graph- or kernel-based methods (Yan *et al.*, 2017), and machine learning approaches (Li *et al.*, 2018; Chaudhary *et al.*, 2018). In regard to the association between transcriptome and a set of regulatory elements

(i.e., regulome), reverse engineering algorithms (Bussemaker, 2006) have been successfully applied in broad researches to infer key regulatory elements (Ouyang *et al.*, 2009; Park *et al.*, 2014; Sasamoto *et al.*, 2016). These algorithms predict a given gene expression profile with features from regulome data as a set of explanatory variables. If the removal test of a variable causes large variance in the predictive model, we should consider that the variable is indispensable factor for regulating the gene expression, which provides clues into further investigations.

Particular regulome data increasingly accumulated in the public domain include TF occupancy, histone modification, DNA methylation, and DNA accessibility. More recently, NGS data capturing higher-order chromatin organization became another omics data showing cooperativity between enhancers and promoters (Dixon *et al.*, 2015; Schwarzer *et al.*, 2017). These have been devoted to the development of databases freely accessible; for example, GTRD (see “Relevant Websites section”), ChIP-Atlas (see “Relevant Websites section”) and Cistrome DB (see “Relevant Websites section”). Meta-analysis of the databases further extends the empirical information of TF binding sites (TFBSs) managed in such as JASPAR (Vlieghe *et al.*, 2006), HOCOMOCO (Kulakovskiy *et al.*, 2013) and TRANSFAC (Wingender *et al.*, 2000). The qualified TFBSs can be extensive resources for online analytical tools (Ho Sui *et al.*, 2005; Okumura *et al.*, 2007; Contreras-Moreira and Sebastian, 2016).

Outlook and Conclusions

Comprehensive cataloging and quantifying RNA population with RNA-seq technique have convinced communities to conduct routine gene expression profiling, giving new opportunities to gain deeper insights into complex molecular interplay and disease development. It is likely that technical innovation in NGS will continue, and RNA-seq will gain more popularity to investigate transcriptome complexity. In parallel, the pervasive utilization of RNA-seq poses significant challenges to the communities, including the management of huge data and knowledge, quantitative and qualitative assessment of outcomes, and standardization of analytical protocols ensuring reproducibility and transparency. Bioinformatics has emerged to deal with these challenges, and recent RNA-seq experiment setting embeds them as an analytical pipeline.

We have described a range of issues in genome-scale scanning of gene expression associated with the intrinsic nature of experimental and computational methods. Although recent community-wide efforts have increasingly guided the effective usage of bioinformatics resources, some of issues still need intensive discussions. This includes statistical designs along with appropriate thresholds; the example of transcriptome analysis demonstrated the influence of FPKM cutoff, thresholds of FC and FDR, and multiplicity correction. Such empirical thresholds directly impact on filtering, mapping, quantifying, and annotating sequenced reads, which indicates the necessity of careful consideration.

We expect future bioinformatics for issues facing the multi-omics data integration to profile the biological functions of key genes that transcriptome analysis detected. Furthermore, continued data opening and sharing are expected for more comprehensive characterization of broad biological consequences; as a line of sequencing projects has instructed, the open innovation coupled with Big Data paradigm will provide valuable resources for systematic reciprocal linking of multiple regulatory layers, and also for linking genotypes to phenotypes. Therefore, effective bioinformatics methods for the integration approaches are becoming more indispensable. Finally, we believe that researchers will actively conduct open sharing of gene expression atlases established by tackling the issues mentioned here, and the atlases will propel genome analysis studies in biological science and clinical setting.

Materials and Methods

Data Preparing

Illumina SRA files for 34 RNA-seq samples were prepared from NCBI GEO; embryonic day E13.5 (GSM1064457), E14.5 (ERP015330), E16.5 (ERP015330), E18.5 (ERP015330), postnatal P0.5 (DRP002386), P2 (ERP015330), P7.5 (DRP002386), Spermatogonia; SG (GSM1069640), Spermatocytes; SC (GSM1069641), Spermatids; SD (GSM1069642), Spermatozoa; SZ (GSM1069643), Mouse embryonic fibroblast; MEF (GSM1643254), and Sertoli; SL (GSM1069639). SRA toolkit (ver. 2.8.2–1) converted the SRA files into FASTQ files by using options “fastq-dump -split-files -A accession”.

Rna-Seq Pipeline

Step1 (Quality control): Trimmomatic (ver. 0.36) assessed all the FASTQ files by using options “ILLUMINACLIP:adapter_file:2:30:10 LEADING:20 TRAILING:20 MINLEN:36”.

Step2 (Mapping): HISAT2 (ver.2.0.5) coupled with Bowtie2 (ver. 2.2.9) mapped the reads of each replicate to the mouse reference genome GRCm38 with options “-k 1 -dta -dta-cufflinks”, resulting 34 BAM files. After gathering unmapped reads from the BAMs by Samtools (ver. 1.5) with options “view -bf 4”, Blastn (ver. 2.2.31) aligned the unmapped reads by using options “-evalue 0.001 -perc_identity 80 -max_target_seqs 1” and a pre-built database with alternative assemblies and contigs downloaded from <ftp://ftp.ensembl.org/pub/> and <ftp://ftp.ncbi.nlm.nih.gov/blast/db/>.

Step 3 (Assembling and Quantifying): Cufflinks (ver. 2.2.1) with options “-total-hits-norm -b GRCm38.fa -G RefSeq(release 80)” assembled transcripts of each BAM, resulting 34 GTF (gene feature format) files. Cuffcompare (ver. 2.2.1) combined the 34

GTFs by using options “-C -T -R -r RefSeq(release 80) -s GRCm38.fa”. Cuffquant (ver. 2.2.1) with options “-b GRCm38.fa Combined_GTF” quantified each BAM and created 34 CBX files. Finally, Cuffdiff (ver. 2.2.1) profiled FPKMs and DEGs from 34 CBXs by using options “-FDR 0.05 -library-norm-method geometric -compatible-hits-norm Combined_GTF All_CBX_files”.

Bioinformatics Analysis

Clustering of gene expression performed R language function hclust; Euclidean distances among FPKMs of samples were adjusted by quantile normalization and mean centering, and the hierarchical average linkage method clustered genes. Sample clustering used Pearson's correlation coefficient as distances. The enrichment analysis of GO terms used the GOC web tool (see “Relevant Websites section”) with the dataset “PANTHER GO-Slim Biological Process”. Bonferroni correction that multiplies P-value of single Binomial test by the number of independent tests calculated FDR represented by Q-value.

Biographical Sketch

Sung-Joon Park received the PhD degree in Engineering from Tokyo Institute of Technology, Tokyo, Japan, in 2005. He has worked as a researcher in Kobe University and Kyoto University. He is currently a senior assistant professor (project) in Human Genome Center, the Institute of Medical Science, the University of Tokyo. He is working on the field of genome information science, and has explored genome features and developed several databases devoted to embryogenesis and stem cell biology. His main research interest is to develop computational ways for interpreting biological information, especially for the functional analysis of gene expression and regulation with high-throughput sequencing data. He is a member of Information Processing Society of Japan (IPSI), The Japan Society for Artificial Intelligence (JSAI), and Japanese Society for Bioinformatics (JSBi).

Metabolome Analysis

Camila Pereira Braga and Jiri Adamec, University of Nebraska-Lincoln, Lincoln, NE, United States

Introduction

Omics strategies have been used in different biological systems to generate knowledge about new biomarkers associated with diagnosis, disease progression, response to treatment (Reichel, 2011), and generally to understand biological processes and their regulation. In the OMICS arena, the proteome represents all proteins expressed in a cell, tissue, or organism, while the genome is associated with the genetic information (Wilkins *et al.*, 1996), the transcriptome with the RNA transcripts, and the metabolome with the metabolites. In this context, the Omics areas are referred to as proteomics, genomics, transcriptomics, and metabolomics. Recently, new terms have been introduced referring either to new areas (interactomics and topomics) or targeting specific class of the molecules (lipidomics and glycomics as a part of metabolomics or degradomics as a part of proteomics) (Nicholson *et al.*, 2007).

The primary focus of this article is on metabolomics – metabolome analysis, the most recently introduced strategy among the Omics. In 1998, Oliver *et al.* (1998) introduced the term metabolome analysis for functional genomics using a yeast model, associating the results of gene deletion or overexpression with the change in the relative concentration of metabolites. That same year, Tweeddale *et al.* (1998) used the term introduced by Oliver *et al.* (1998) (metabolome analysis) in analyzing *Escherichia coli* cell metabolites for phenotypic profiling. One year later, Nicholson *et al.* (1999) defined the term metabonomics as the “quantitative measurement of the dynamic multiparametric metabolic response of living systems to pathophysiological stimuli or genetic modification”.

In 2001, such terms were clearly defined by Fiehn: metabolomics – the “metabolome of the biological system under study,” metabolic fingerprinting – “a rapid classification of samples according to their origin or their biological relevance,” metabolite profiling – the investigation of pre-defined metabolites (based in their association with a specific pathway or class of compounds), and metabolite target analysis – which aims “to study the primary effect of any alteration (e.g., a genetic mutation) directly” (Fiehn, 2001). Other terms have also appeared throughout the years, such as metabolic footprinting, which refers to exo metabolomes and secretomes (metabolites in extracellular fluids) (Kell *et al.*, 2005).

Metabolomics analysis can be categorized into two approaches, targeted and untargeted metabolomics. In targeted metabolomics, the metabolites selected for quantification are known and represent specific pathway(s) or class(es) of molecules. Untargeted metabolomics, on the other hand, is used to determine as many metabolites as possible and involves both metabolites quantification and their identification. (Cambiaghi *et al.*, 2017). Targeted metabolomics refers to absolute quantification (nM or mg mL⁻¹), specifically by using an internal standard and semiquantitative or quantitative analysis to detect known compounds related to specific pathways defined *a priori*, based on the hypotheses of the study (Roberts *et al.*, 2012; Cambiaghi *et al.*, 2017). Untargeted metabolomics refers to the measure of all possible metabolites in a sample using relative quantification (fold change), and comparison between samples (Roberts *et al.*, 2012; Cambiaghi *et al.*, 2017). The challenges of untargeted metabolomics are metabolite identification, characterization of unknown small molecules, and the time needed to process the generated data (Roberts *et al.*, 2012).

Metabolome Analysis

Metabolome analysis involves several steps, as indicated in Fig. 1. The study starts with an experimental design that consists of two main steps (Goodacre *et al.*, 2007). The first step is to define the biological problem, generating the hypotheses of the study. Based on that, the second step involves various metabolomics approaches used in the analysis. These steps typically include sample preparation, sample analysis and data acquisition, data preprocessing, and data statistical analysis and interpretation.

Sample Preparation

Sample preparation is an important step in metabolome analysis, consisting of sample collection and metabolite extraction. Metabolite extraction depends on the sample type (cell, biological fluid, or tissues), the metabolomics approach defined in the experimental design, and can involve steps such as quenching (removal of proteins and their enzymatic activities by denaturation and precipitation), use of internal standards, and optional derivatization of specific classes of metabolites (Klassen *et al.*, 2017).

In the quenching step, the inactivation of the cellular metabolic and enzymatic activities is achieved by sample exposure to an acidic or alkaline solution, or/and cold (< –40°C) or hot solutions (Villas-Bôas *et al.*, 2006). Some examples are the use of cold methanol, liquid nitrogen, and perchloric acid. The choice of the method(s) usually depends on the stability of the metabolites targeted for analysis. If, for example, metabolites of interests are not stable at higher temperature or low pH, hot solution or acids are avoided in quenching steps. Liquid nitrogen and cold methanol are usually used for untargeted metabolomics as they represent relatively mild conditions and have a minimal impact on the stability of samples. The quenching step is often combined with extraction. For example, performing an extraction of both biomass and media will allow a simultaneous intracellular and

Fig. 1 Metabolome analysis workflow.

extracellular analysis. On the other hand, prior separation of the cellular components by, e.g., centrifugation will permit an intracellular analysis without the interference of extracellular compounds (Villas-Bôas *et al.*, 2005).

The most common solvents used to extract metabolites are organic solvents: polar solvents (methanol, ethanol, and mixtures of methanol-water) are used to extract polar metabolites, while non-polar solvents (chloroform, hexanes, and ethyl acetate) are employed to extract lipids (Villas-Bôas *et al.*, 2005, 2006). The selected extraction method should obtain the maximum quantity of intracellular metabolites to avoid loss of metabolites, and to be compatible with the analytical tools used for their quantification and identification (Villas-Bôas *et al.*, 2005, 2006). The concentration step (freeze-drying and reducing volume under vacuum using e.g., roto-vac) is recommended when an extraction method is used, as sample dilution can decrease metabolite concentrations under the detection limits, and affect the sensitivity and overall results. Furthermore, it is possible to analyze the metabolites of interest by using solid-phase extraction (SPE) and solid-phase micro-extraction (SPME) to concentrate the intracellular metabolites from a diluted sample.

Protein precipitation is an important step that removes proteins present in the sample, extracting the metabolites that can non-covalently bind to proteins by , and preserving the column when using liquid chromatography (LC) as an analytical method (Bruce *et al.*, 2008).

The derivatization step is particularly important in Gas Chromatography – Mass Spectrometry (GC–MS) based analytical techniques as the GC can separate only volatile compounds (Garcia and Barbas, 2011). In this case, silylation, alkylation, or other derivatization reactions can convert non-volatile compounds to volatile ones.

Microbial sample preparation

Winder *et al.* (2008) studied different methods of sample quenching by evaluating 60% aqueous methanol (-48°C), tricine-buffered (0.5 mM, pH 7.4) aqueous 60% methanol solution (-48°C), and boiling with ethanol (90°C); in combination with various extraction steps including 100% methanol (-48°C), methanol/chloroform (2:1), perchloric acid (0.25 M), and boiling with ethanol (90°C) and potassium hydroxide (0.25 M, 80°C). The study concluded that the procedure utilizing 60% aqueous methanol (-48°C) to quench the metabolism, and extraction with 100% methanol (-48°C) were the most appropriate methods to extract intracellular metabolites in *Escherichia coli* cultures (Winder *et al.*, 2008). Li *et al.* (2013) found that the most appropriate quenching method for *Bacillus licheniformis* consisted of perchloric acid rather than hydrochloric and phosphoric acids. Another study suggested a cold glycerol-saline solution as a quenching method for analyzing intracellular metabolites in microbial cell cultures (e.g., *Pseudomonas fluorescens* – a gram-negative bacterium, *Streptomyces coelicolor* – a gram-positive bacterium, and *Saccharomyces cerevisiae* – baker's yeast) (Villas-Bôas and Bruheim, 2007).

Plants tissue sample preparation

The most common method used as for quenching to extract metabolites in plants after harvesting is snap-freezing the plant tissue with liquid nitrogen, and subsequent storage at -80°C (Jorge *et al.*, 2016). In the extraction step, the most common solvents are chloroform, methanol, and water (2:1:1, v/v) to separate lipophilic (non-polar) and hydrophilic (polar) metabolites (Verpoorte *et al.*, 2008).

Animal tissue sample preparation

For animal and human tissues, the primary methods used to quench metabolism are snap-freezing in liquid nitrogen and cold methanol (Stentiford *et al.*, 2005; Wang *et al.*, 2011). For the extraction of polar and non-polar metabolites, chloroform and methanol (2:1, v/v) has been demonstrated to be the most efficient solvent (van Ginneken *et al.*, 2007; Atherton *et al.* 2008).

Sample Analysis and Data Acquisition

Common analytical platforms employed for data acquisition in metabolome analysis are nuclear magnetic resonance (NMR) and mass spectrometry (MS) analysis, typically coupled with separation techniques such as gas chromatography (GC), high or ultra-performance liquid chromatography (HPLC or UPLC), or capillary electrophoresis (CE).

NMR based metabolomics

NMR is a relatively robust technique which is typically applied to studies such as metabolite fingerprinting, profiling, and metabolic flux analysis, involving different samples such as cell extracts, cell cultures, tissues, and biofluids. NMR is based on spin behavior of atomic nuclei in magnetic field which is represented by the resonance frequency. NMR is nondestructive, noninvasive and nonequilibrium method requiring minimal or no sample preparation to analyze various metabolites in the micromolar range (Reo, 2002; Beckonert *et al.*, 2007). As NMR is a noninvasive method, it has been also used extensively in metabolomics analysis to diagnose diseases (Brindle *et al.*, 2002; Gowda *et al.* 2008; Capati *et al.*, 2017).

NMR in metabolomics analysis exhibits highly reproducible and quantitative characteristics; molecular properties such as hydrophobicity and acid dissociation constant (pKa) do not influence NMR sensitivity (Pan and Raftery, 2007). The limitations of NMR in metabolomics analysis are due to poor sensitivity and spectral resolution (minimum spectral distance between two distinguishable peaks) that can compromise metabolite identification in complex samples. The sample preparation is the same for the most types of samples. To generate good NMR data, it is necessary to add an internal chemical shift standard, a phosphate buffer solution, and deuterated water (D_2O , the latter of which is used as a lock frequency for long-term magnetic field drifts (Heude *et al.*, 2017).

The most common NMR spectroscopic methods used to quantify metabolites are one-dimensional proton NMR spectroscopy (1D NMR) and two-dimensional proton J-resolved NMR spectroscopy (2D Jres NMR). The advantages of 1D NMR are to provide a relatively good quantitative profile of the metabolites and rapid spectral acquisition. In addition, a single standard can be used for absolute quantification of the measured metabolites (Huang *et al.*, 2015). On the other hand, the only more abundant metabolites can be detected (concentrations $> 1\text{--}10\ \mu\text{M}$), and peak overlap hinders metabolite identification (Gebregiworgis and Powers, 2012). 2D-1H Jres can partially resolve the peak overlaps observed in 1D-1H NMR by determining the peak intensity and properties, using the separation of chemical shifts and *J* coupling in two spectral dimensions to improve metabolite identification (Huang *et al.*, 2014, 2015).

MS based metabolomics

In comparison to NMR, MS is more sensitive and specific. Furthermore, the increase in coverage of the metabolite analysis can potentially lead to the detection of thousands of metabolites. Every mass spectrometer consists of three integrated parts including 1/a ionization source that adds charge to molecules to be analyzed, 2/a mass analyzer that separates molecules based on their mass/charge ratio (*m/z*), and 3/a detector. Although direct injection is a rapid technique, often used in metabolomics analysis (in both targeted analysis and metabolite profiling – to quantify metabolites and elucidate metabolite structure), the major limitation is associated with low and inconsistent ionization efficiencies in complex biological samples (Zhang *et al.*, 2012).

Therefore, the best results are achieved by using separation techniques such as GC, HPLC/UPLC, and CE (Zhang *et al.*, 2012) prior to MS analysis. Although this can be done using off-line separation followed, by MS analysis of individually collected fractions, an in-line setup that couples the separation and MS steps into one system is preferred, and leads to better results.

GC-MS metabolomics

GC-MS in metabolomics analysis can separate and detect volatile metabolites that occur naturally (alcohols, aldehydes, esters, etc.), or metabolites that become volatile after derivatization (semi-volatile metabolites – amides, amines, amino acids, sugars, organic acids, peptides, and lipids; and nonvolatile metabolites that are chemically modified to increase their stability in the high temperatures used in GC-MS analysis) (Villas-Bôas *et al.*, 2005; Zhang *et al.*, 2012). Over the years, the GC-MS approach has demonstrated robustness, high reproducibility, and it is relatively inexpensive (Villas-Bôas *et al.*, 2005; Zhang *et al.*, 2012). The basic principle of GC separation is based on the partition of specific molecules between gas and liquid phases at a given temperature, and the effect of the portioning on their movement through the GC column. Molecules in the gas phase move through the GC capillary column and are subsequently detected by MS. Because the molecules have different volatility, and partition differently between the gas and liquid phases depending on the temperature, applying an increasing temperature gradient on the GC column allows for the separation of molecules in time. GC capillary columns are selected based on the metabolite characteristics, such as polarity or volatility (Villas-Bôas *et al.*, 2005). For semi-volatile and non-volatile metabolites, the derivatization step needs to be included in the sample preparation. The methods used for derivatization include usually silylation (especially used with sugars – amino sugars, sugar alcohols, and phosphorylated sugars), and alkylation or esterification (used with polyfunctional amines and organic acids) (Villas-Bôas *et al.*, 2005). For untargeted metabolite profiling, the GC-MS approach involves sample extraction, sample derivatization and separation by GC, and ionization of the separated molecules, followed by detection and data evaluation (Kopka *et al.*, 2004). For targeted analyses, additional steps such as extraction with an organic solvent to enrich specific classes of metabolites, or adjustment of separation conditions, such as the use of long capillary columns (30–60 m), or/and sample injection at various, sample specific, temperatures may be necessary (Villas-Bôas *et al.*, 2005).

Using GC-MS techniques, Lv and Yang (2012) found potential biomarkers of breast cancer in free fatty acids (palmitic acid, stearic acid, and linoleic acid) using serum samples analyzed by GC-MS. Changes in sn-glycerol-3-phosphate in lipid metabolism were found in metabolomics analysis by GC-MS when comparing breast cancer and normal tissues (Brockmöller *et al.*, 2012). In addition, Dória *et al.* (2012) found lysophospholipids and saturated fatty acids in phosphatidylinositols using an Electrospray Ionization Mass Spectrometry (ESI-MS) and cell culture model. In 2012, Nishiumi *et al.* (2012) used GC-MS to analyze a serum-targeted metabolome in Colorectal Cancer (CRC) patients, and found 2-hydroxybutyrate, aspartic acid, kynurenine, and cystamine as potential biomarkers for early detection. Years later, the use of NMR-based fecal metabolomic fingerprinting in CRC patients led to the observation of reduced levels of acetate, butyrate, propionate, glucose, glutamine, and elevated quantities of succinate, proline, alanine, dimethylglycine, valine, glutamate, leucine, isoleucine and lactate. The changes in metabolite levels between samples from CRC patients and the control group can be associated with malabsorption of nutrients, disturbance in the bacterial ecology, and increased glycolysis and glutaminolysis (Lin *et al.*, 2016).

LC-MS metabolomics

In LC-MS, liquid samples are directly injected into the LC column and metabolites are separated based on their interaction with a stationary phase prior MS detection. The stationary phase is usually represented by spherical beads covered on the surface with specific functional groups that define the nature of the separation. Whilst polar metabolites are typically separated by ion exchange or Hydrophilic Interaction Chromatography (HILIC) columns, non-polar metabolites are separated by their hydrophobicity on Reverse Phase (RPLC) columns (C4, C8, or C18). Non-hydrophobic molecules without charge can be separated by Normal Phase Liquid Chromatography (NPLC). In all cases, the metabolites retained on the column are eluted by a solvent that disrupts metabolite-stationary phase interactions, and leads to metabolite release. NPLC uses a solvent with a higher polarity than that of the stationary phase (nonpolar are eluted first), whereas RPLC uses a solvent with a lower polarity than the stationary phase (Lopes *et al.*, 2017). The ionization techniques applied in LC-MS are electrospray ionization (ESI), atmospheric pressure chemical ionization (APCI), and atmospheric pressure photoionization (APPI). These ionization processes do not modify or fragment biomolecules and therefore are considered to be soft ionization techniques. Although the most common technique is ESI (Villas-Bôas *et al.*, 2005; Lopes *et al.*, 2017), APPI and APCI are primary techniques that are used to analyze metabolites with limited ESI efficiency, such as Vitamin D and its metabolites (Adamec *et al.*, 2011).

The major difference between untargeted and targeted LC-MS approaches is the MS parameter setup. Untargeted metabolomics is designed to detect as many metabolites as possible, therefore the instrument is optimized for a broad range of molecular masses (m/z), typically set to 50–2200 m/z . Targeted metabolomics, on the other hand, is optimized for maximum sensitivity at the specific m/z of metabolite(s) of interest. Currently, two types of MS instruments, QQQ and qTRAP, are almost exclusively used for targeted analysis using techniques known as Selected Reaction Monitoring (SRM) and Multiple Reaction Monitoring (MRM). In these techniques, data is acquired from one or more specific product ions generated by fragmentation of selected precursor ion(s) (metabolite(s) of interest), with known m/z , using a multi-stage mass spectrometer (QQQ or qTRAP) (Hoffmann, 1996). In first stage, only ions with defined m/z are allowed to pass through to the second stage, in which the precursor ion is fragmented. In the third stage, only the intensities of fragments (product ions) corresponding to the original precursor ion are monitored and used for quantification.

LC-MS techniques are widely used in many biological studies. For example, using an untargeted metabolomic analysis of serum samples with 300 Type 2 Diabetes (T2D) patients and 300 healthy controls by UPLC-MS, the authors found lipids, hexose sugars, and

purine nucleotides as biomarkers of T2D (Drogan *et al.*, 2015). Metabolomics studies conducted in Alzheimer's patients plasma samples identified desmosterol as a potential biomarker (Sato *et al.*, 2012). Although, LC-MS is very powerful tool, to increase a number of identified metabolites, the approach is often combined with GC-MS. Using both, LC-MS and GC-MS, lysophosphocholine, tryptophan, phytosphingosine, dihydrosphingosine, hexadecosphinganine, arachidonic acid, *N,N*-dimethylglycine, thymine, glutamine, glutamic acid, and cytidine were also identified as potential biomarkers of Alzheimer disease (Li *et al.*, 2010; Wang *et al.*, 2014).

Capillary electrophoresis (CE)-MS metabolomics

CE-MS is a separation technique that uses capillary electrophoresis to achieve high efficiency and selectivity, peak capacity (by resolving more peaks), fast analysis, and small sample volume, to analyze polar and ionic compounds without a derivatization step (Ramautar *et al.*, 2009). This technique can be used to analyze targeted and untargeted metabolites, such as amino acids, carbohydrates, vitamins, thiols, peptides, and nucleotides (Villas-Bôas *et al.*, 2005).

In CE, capillary zone electrophoresis (CZE), in which separation is based in differences in electrophoretic mobilities (neutral compounds are not separated), is the most used mode. Other modes include micellar electrokinetic chromatography (MEKC, separation of neutral compounds is possible), capillary isoelectric focusing (CIEF, where a pH gradient is used to separate amphiprotics), capillary isotachopheresis (CITP, for separation of small molecules and ions), capillary gel electrophoresis (CGE; large molecules and polymers can be analyzed using gels), and affinity capillary electrophoresis (ACE, which is based on biospecific interactions) (Rodrigues *et al.*, 2017).

Data Processing and Analysis

A critical component of any metabolomics platform is the link between the generation of data and realization of the value it contains. This link is filled with various bioinformatics and statistical tools specifically designed for metabolomics data mining. The individual steps involved in this process are typically data preprocessing, normalization, data pretreatment, and statistical analysis with interpretation and visualization (Figs. 2 and 3) (Karaman, 2017).

Fig. 2 MS data processing workflow.

Fig. 3 NMR data processing workflow.

MS data preprocessing

Data generated by MS are collected in vendor proprietary data formats, and to be processed by vendor independent software packages, they need to be converted into standardized file formats such as mzData, mzXML or mzML (Karaman, 2017). Following the conversion, data is processed by various data preprocessing software packages (Table 1) to generate a single sample file in which characteristics such as m/z, retention time, and ion intensity can be accessed for each ion (Katajamaa and Orešič, 2007). The process consists of several steps including (but not limited to) generation of a peak list, optional peak list filtration, and removal of isotopes (as each compound (metabolite) is represented by several isotopic peaks). For processing of LC- and GC-MS data, chromatograms must be generated for individual peaks and results deconvoluted (separating signals corresponding to real metabolites from instrument interferences). These steps are used to generate extracted MS spectra and chromatograms that can be employed for metabolite identification, and to calculate relative concentrations, respectively (Katajamaa and Orešič, 2007). In addition, the generation of chromatograms and spectrum deconvolution help to differentiate signals that originate from the actual analytes, or from contaminants or instrumental noise, and reduce data dimensionality, to simplify statistical analysis and data interpretation.

Peak picking is the first step in data preprocessing. In this step, every peak (ion) detected in the sample is defined (assigned) by its m/z value and, in the case of LC- or GC-MS, by retention time (RT).

To compare multiple LC- or GC-MS analytical runs, a peak alignment step must be used. In a perfect case, the same metabolites from different samples, detected by the same analytical system, should have the same retention time and m/z (molecular mass). Due to the experimental variation and minor changes in analytical conditions, that is not usually the case. The objective of peak alignment is to distinguish the peaks of the same molecule, occurring in different samples, from the thousands of peaks detected during the course of an experiment. Alignment is therefore applied to correct retention times and to detected molecular mass variations between runs. Various strategies are used to carry out this step such as aligning detected peaks by the match score (join aligner), or by comparing individual peak lists with the master peak list, which is usually generated from the average of all aligned peak lists (Katajamaa and Orešič, 2007). Additional methods that may help to resolve and sort the data include summation or binning of chromatographic data, curve resolution, and gap filing (Nordström et al., 2006). The gap filling is particularly important step in analysis of larger number of very complex samples as peaks can be missed during peak picking step in some samples, primarily due to low intensity or/and irregular chromatographic peak distribution. When this occurs, preprocessing algorithms can be employed to search for the peak structures in the raw data and assign missing values (Karaman, 2017).

NMR data preprocessing

Currently, many software packages are available (**Table 1**) to transform NMR raw data to an appropriate form for the subsequent processing steps, including baseline correction, peak alignment, and binning.

Baseline correction is applied to differentiate real peaks from instrumental noise. The most used baseline correction approaches is the frequency or time domain method, which can be easily applied to metabolomics spectra, subtracting a baseline estimation from the measured spectrum (Euceda *et al.*, 2015). Additional procedures that employ steps such as noise removal and/or smoothing include iterative polynomial fitting and asymmetric least squares smoothing (AsLS) (Euceda *et al.*, 2015).

During a relatively long time of NMR data acquisition process, resulting chemical shift can be affected by changes in pH, temperature and/or molecular interactions in the samples. This, in turn, creates a small variation in ppm spectra in different samples. Peak alignment methods are used to correct these differences. The alignment can be global (parametric time warping – PTW), in which the total spectrum is corrected, or the alignment can be carried out in each segment separately (correlation optimized warping – COW; icoshift) (Euceda *et al.*, 2015; Karaman, 2017).

The binning step is important in facilitating data analysis through the reduction in the number of variables. In this case, the spectra generated in NMR are segmented into various bins and signal in each bin is calculated by the integration. This may, however, lead to the loss of resolution or/and to the risk of splitting a peak (Vu and Laukens, 2013; Karaman, 2017). Therefore, depending on the data, binning methods can be of equal size (0.005 and 0.05 ppm), or bin size can be determined for each interval, and the bins can represent either individual peaks or a groups of peaks (Euceda *et al.*, 2015; Karaman, 2017).

Normalization

To minimize experimental variation in multi-sample quantitative analyses, it is necessary to normalize the data. Although several normalization methods including auto-scaling, use of a reference sample, log linear model, trimmed constant mean, and average intensity are available in software packages, the choice of the best method depends on the type of study and complexity of the samples. For example, by the addition of internal or external standards – samples can be normalized using the peak area/intensity of the known standard (Karaman, 2017). However, this method controls for variation due to sample preparation and analysis (technical variation), but not the sampling itself. Statistical models, on the other hand, allow one to normalize each sample with optimal scaling factors based on the complete database (Crawford and Morrison, 1968) in accordance with the unit vector norm generated by scaling each sample vector (variable – ion) (Scholz *et al.*, 2004) or median (Wang *et al.*, 2003) intensities, or by the maximum likelihood method (Orešič *et al.*, 2004), without any internal/external standards.

Data pretreatment

Another very useful tool, particularly for extraction of relevant biological information and for results interpretation, is data pretreatment (van den Berg *et al.*, 2006). Complex samples contain thousands of metabolites with concentrations covering enormous dynamic range (difference between low abundant and high abundant metabolites). Problem is that changes in cellular function (phenotype) is often not proportional to the fold change and overall abundance of the metabolites. For example, regulatory molecules usually exist in very low concentrations and small fold change have tremendous impact on the cell behavior (induced proliferation, cell survival etc.). Structural molecules, on the other hand, can be present in high concentrations or significant fold change may have only a minimal impact for overall cellular functions. To correct for these disproportion, data pretreatment methods can be used. These methods usually consist of centering, scaling, and data transformation. In centering, the mean that centers the differences between the samples (high and low abundant metabolites) is adjusted, leaving only the relevant variation (van den Berg *et al.*, 2006). In scaling, each variable is divided by the scaling factor, leading to an adjustment in the fold differences in the various metabolites (van den Berg *et al.*, 2006). Scaling can be based on data dispersion measured as a scaling factor. In autoscaling, metabolites are scaled based on standard deviation and all metabolites become equally important. Pareto scaling, on the other hand, reducing the relevant importance of large values. It is based on standard deviation, however, larger changes are scaled less than small changes. Similarly, Vast scaling focusing primarily on metabolites with small fluctuations. Level scaling uses the mean concentration as the scaling factor emphasizing relative response and therefore ideal for biomarker discovery (van Ginneken *et al.*, 2007; Karaman, 2017). Data transformation consists of eliminating heteroscedastic noise. (van Ginneken *et al.*, 2007). The most common transformations used are nonlinear transformations, such as log transformation, for which multiplicative noise is converted to additive noise, and power transformations, in which the original data is replaced by the calculated square root. (van Ginneken *et al.*, 2007; Karaman, 2017). It is important to note, that the selection of the data pretreatment methods can significantly affect the interpretation of results the metabolomics studies, and strongly depends on the biological question to be answered, the properties of the data, and the statistical analysis applied to the pretreated data. Inappropriate choice of these methods can lead to data misinterpretation.

Statistical Analysis

To find significant differences among the sample groups, basic statistical methods are usually a part of metabolomics data analysis software packages. Statistical significance tests identify data elements that make significant contributions to the protein and/or metabolite profile of a sample, or that distinguish a group of samples from others.

Phenotypic grouping is also an important tool for the investigation of the underlying interrelationships within a large data set. Statistical methodologies that identify these groups or clusters are known as clustering techniques, and originate from multivariate statistics. Hierarchical clustering can be used to sort data out into previously unknown clusters. Clustering objects on subsets of attributes (COSA) is an unsupervised method to cluster samples, that is an enhancement to distance based clustering methods (Friedman and Meulman, 2004). COSA detects groups of objects that have preferentially close values in different, possibly overlapping, subsets of attributes. Other clustering methods such as Principal Component Analysis (PCA), k-means clustering, and self-organizing maps (SOM) are also included in many software packages. Multivariate analyses such as Principal Component Analysis (PCA), Partial Least Squares-Discriminant Analysis (PLS-DA), and Orthogonal Projection to Latent Structures (OPLS-DA), can be employed to corroborate applied univariate analyses, such as t-tests, Kruskal Wallis tests, Mann Whitney tests, and ANOVA (Alonso *et al.*, 2015). Unsupervised methods are often used to explore, summarize and find hidden relation between the data (Liland, 2011). For example, to detect pattern correlated with experimental conditions or disease, or to assess data quality, PCA can be used. In this case, PCA is considered as the unsupervised methods pointing out various sample patterns (Liland, 2011).

PLS-DA and OPLS-DA, on the other hand, are supervised methods (OPLS-DA was developed to improve PLS-DA) used to discriminate known classes (e.g. control vs disease). Unlike unsupervised methods, these methods are applied to classify, predict, and discover potential biomarkers (Ren *et al.*, 2015).

Metabolite Identification and Pathway Visualization

Metabolite identification is necessary for untargeted metabolite analysis, since the metabolites of interest are unknown when the biological problem is defined. The list of possible metabolites can be generated using free databases and libraries, using either measured molecular mass (m/z) of the unknown metabolites and their retention time (for LC- or GC-MS data), or from chemical shifts and coupling constants (for NMR data) (Moco *et al.*, 2007). Common databases and libraries used in metabolomics include the Human Metabolome Database (HMDB), Spectral Database for Organic Compounds (SDBS), Comprehensive Species-Metabolite Relationship Database (KNapSack), Metlin, Golm Metabolome Database, MassBank, MassTRIX, PubChem, ChEMBL, Chemical Entities of Biological Interest (ChEBI), BioMagResBank, and Kyoto Encyclopedia of Genes and Genomes (KEGG) (Fig. 4) (Moco *et al.*, 2007; Klassen *et al.* 2017). For LC-MS experiments, the molecular mass of the metabolite is not sufficient for final identification as many compounds may have the same molecular mass, but differ in atomic composition and structure. Therefore, additional experiments using MS/MS techniques are necessary to analyze the fragmentation patterns of the metabolites of interest and their correctly identify them.

The final step in data analysis and interpretation is the visualization of the results, and identification of pathways associated with the biological response or regulation. The databases commonly used are the Kyoto Encyclopedia of Genes and Genomes (KEGG), MetaCyc, the Small Molecule Pathway Database (SMPDB), MetaboLights, and Reactome (Fig. 4).

Fig. 4 Metabolite identification and data interpretation.

Applications

Metabolomics analyses have been applied in various research fields, such as medical research (diseases), plant biology, microbiology, toxicology, sustainable energy research etc. The focus primarily centers on the changes in the metabolite concentration, or their flux in specific pathways. Metabolomics data is important to the discovery of new biomarkers that can be associated with early diagnosis, progression, response to treatment, and to understand basic cellular processes and their regulation.

Metabolomics in Disease

In cancer, metabolomic analysis can be used to help to directly diagnose cancer stages from bodily fluids or histological samples. Colorectal cancer (CRC) is the third most commonly diagnosed cancer after lung and breast cancers; it also represents the fourth highest cancer-related cause of death (Siegel *et al.*, 2017).

Qiu *et al.* (2009) combined two analytical techniques, GC-MS and LC-MS, to analyze the serum metabolome of patients with CRC. Collected serum samples were spiked with internal standards L-2-chlorophenylalanine and heptadecanoic acid, and metabolites were extracted with methanol/chloroform (3:1 ratio (v/v)). First, the sample aliquots were derivatized using methoxyamine and BSTFA, followed by injection and metabolite separation using a DB-5 ms capillary column (30 m × 250 μm, 0.25 μm film thickness) in GC-MS system (Agilent 6890N gas chromatography instrument coupled with a Pegasus HT time-of-flight mass spectrometer from Leco Corporation). MATLAB 7.0 was used to convert the acquired data to netCDF format, and the ChromaTOF software was used to perform data processing. For LC-MS (Acquity ultra performance liquid chromatography MS system, Waters) analysis, the serum samples were spiked with the internal standard L-2-chlorophenylalanine and metabolites extracted using methanol/acetonitrile (5:3 ratio (v/v)). Samples were injected into a 1.7-μm BEH C18 column and run in both positive and negative mode. Data acquisition was performed using the MassLynx software. The SIMCA-P software was used for PCA and OPLS-DA statistical analysis, in which CRC and healthy controls patients were compared. NIST MS Search 2.0 was used for metabolite identification. Five metabolites, including pyruvate, lactate, tryptophan, tyrosine, and uridine, were identified by both analytical techniques as potential biomarkers, and indicated perturbation in glycolysis, arginine, and proline metabolism, as well as in the metabolism of fatty acids (Qiu *et al.*, 2009).

Urine is a biofluid commonly used in metabolomic analysis to identify biomarkers. Using urine samples and both GC-MS and LC-MS platforms, Cheng *et al.* (2012) identified citrate, hippurate, p-cresol, 2-aminobutyrate, myristate, putrescine, and kynurenate as potential biomarkers of CRC. Results suggest that the urinary metabolome of patients with CRC is potentially altered by metabolites derived from gut microbe-host co-metabolism (Cheng *et al.*, 2012).

In another study, using urine samples from 401 patients with clinically diagnosed Parkinson's disease, 106 patients with idiopathic Parkinson's disease, and 104 healthy control participants, metabolome analysis was carried out by LC-MS (Luan *et al.*, 2015). Urine samples were precipitated with methanol, and the supernatant injected in an LC-MS (Shimadzu Prominence LC system) coupled online to an LTQ Orbitrap Velos instrument (Thermo-Fisher Scientific), with which samples were analyzed in both positive and negative mode. Data analysis was conducted using XCMS and CAMERA software, with the R statistical package. The OPLS-DA and Human Metabolome Database were used to identify possible biomarkers, which included cortisol, 11-deoxycortisol, 21-deoxycortisol, histidine, urocanic acid, imidazoleacetic acid, and hydroxyphenylacetic acid (Luan *et al.*, 2015).

Rizza *et al.* (2014) used metabolic profiling to identify predictors of major cardiovascular events in elderly people. In this study, the samples were extracted with 75% methanol and 0.01% oxalic acid containing stable isotope internal standards. The samples were analyzed by direct infusion mass spectrometry (DIMS) using a Quattro Ultima Pt ESI tandem quadrupole mass spectrometer (Waters). Data analysis was performed with MassLynx v4.0 and NeoLynx software. The PCA statistical analysis revealed medium- and long-chain acylcarnitines, and alanine as potential biomarkers (Rizza *et al.*, 2014).

NMR was used to identify biomarkers of depressive disorder in urine samples (Zheng *et al.*, 2013). The study involved 82 first-episode drug-naïve patients and 82 healthy controls. Urine samples were first centrifuged, and the supernatant mixed with phosphate buffer in 90% D₂O. Data was collected on an Avance II 600 (Bruker) spectrometer using a frequency of 600.13 MHz ¹H and processed by the AMIX package (Bruker). Supervised OPLS-DA with a multivariate approach revealed formate, malonate, N-methylnicotinamide, m-hydroxyphenylacetate, and alanine as biomarkers of the disease (Zheng *et al.*, 2013).

Metabolomics in Plant Biology

Metabolomics studies in plants typically investigate the presence of biomarkers related to plant development, growth, and response to different environmental conditions and stressors.

Vaclavik *et al.* (2013) used two platforms, the Acquity UPLC system equipped with a reversed-phase analytical column for UHPLC–QqQ/LIT-MS and an AccuTOF–LP-TOF-MS for direct analysis in real time – mass spectrometry (DART–MS), to identify biomarkers of cold tolerance (Vaclavik *et al.*, 2013). In this study, metabolic fingerprints of three groups including a control group (plants growing at room temperature), cold acclimated group (plants exposed to –4°C for 2 weeks), and slow cooling group (plants exposed to –4°C for 8 h) of *Arabidopsis thaliana* were compared and evaluated. The metabolites were extracted using methanol (50 mg tissue/mL) and analyzed by UHPLC–QqQ/LIT MS. The acquired data was processed by the MarkerView software (AB SCIEX), using PCA and a *t*-test to compare the peak intensities among the groups. In addition, the DART–MS data was processed by the Mass Center software (version 1.3, JEOL), and STATISTICA software (version 8.0, StatSoft) was used for the PCA statistical analysis. To identify the structure of significantly affected metabolites, the authors used the MassLynx software (Waters), and isotope distribution, to estimate elemental composition (Vaclavik *et al.*, 2013). Whilst gluconapin was demonstrated to be biomarker of the cold sensitive phenotype, kaempferol-3,7-O-dirhamnoside and kaempferol-3-neohesperidoside-7-O-rhamnoside were identified as the biomarkers of high cold tolerance (Vaclavik *et al.*, 2013).

The plant metabolomics is associated with a high diversity of secondary metabolites also known as phytochemicals. Nakabayashi *et al.* (2009) studied *Arabidopsis thaliana* as a model for genome research, using non targeted metabolomics by 1D and 2D NMR, HRFABMS, FT-ESI-MS and GC–TOF-MS techniques. To maximize metabolome coverage, reduce the sample complexity, and enrich specific classes of metabolites, the authors used a series of extraction methods including methanol, n-hexane, ethyl acetate, chloroform containing 5% methanol and n-butanol. For example, the anthocyanin fraction was obtained by n-butanol extraction. A total of 37 compounds such as apocarotenoids, anthocyanins, carotenoids, chlorophyll derivatives, dicarboxylic acids, flavonols, galactolipids, glucosinolate, icosane, steroid, phenylpropanoids, and nucleosides were identified in this study (Nakabayashi *et al.*, 2009).

Metabolomics in Microbiology

Metabolomics in microbiology is a very important tool for understanding basic biological questions such as those for which microbes have been used as model organisms for many years. Recently, many studies also have focused on the improvement of microbes to produce alternative sources of energy, or to better understand microbial resistance to various antibiotics and identify new drug targets.

Ledala *et al.* (2014) used NMR as an analytical technique to investigate influence of iron and oxygen limitations on the metabolism of *Staphylococcus aureus*. Samples from two growth phases were harvested in this study, exponential (2 h) and post-exponential (6 h). Altogether, eight and four replicates, respectively, were used for one-dimensional ¹H NMR and two-dimensional ¹H-¹³C heteronuclear single quantum coherence (¹H-¹³C HSQC) analyses. The samples were quenched in liquid nitrogen, and bacteria were collected using ice-cold 20 mM phosphate buffer. TMSP-d₄ (3-(trimethylsilyl)propionic acid-2,2,3,3-d₄) was used as an internal standard for both ¹H NMR and ¹H-¹³C HSQC experiments. For ¹H NMR, the data was processed and analyzed by ACD/1D NMR manager version 12.0 (Advanced Chemistry Development), and ¹H-¹³C HSQC data were processed using the NMRPipe software package. To identify the significant metabolite changes, *t*-tests, PCA, OPLS-DA, and unique structure (SUS) calculations were performed using the SIMCA 12.0_statistical package (Umetrics). Metabolite identification was achieved by comparison of measured chemical shifts with the chemical shift references from Human Metabolomics Database, Platform for RIKEN Metabolomics (PRIME), and Biological Magnetic Resonance Data Bank (BMRB). The most significant changes in metabolite concentrations were found in the post-exponential phase, and were associated with the TCA cycle (Ledala *et al.*, 2014).

Stipetic *et al.* (2016) investigated differences in the metabolome of the planktonic and biofilm states of *Staphylococcus aureus*. The sample extraction was performed using chloroform/methanol/water (1:3:1 ratio (v/v/v)), followed by LC-MS analysis using a hydrophilic interaction liquid chromatography (HILIC). The MS data was analyzed using several packages including XCMS (peak picking), mzMatch (filtering and grouping), and R-scripts (filtering, post-processing and identification). In the statistical analysis step, PCA was implemented to compare the two states. Affected pathways were visualized in the KEGG, and suggested that the most prominent changes are in arginine biosynthesis (Stipetic *et al.*, 2016).

Closing Remarks

Metabolomics is the most recent OMICS strategy, and is being used to understand the molecular mechanisms of cellular processes in various biological systems. Whilst proteomics data determines the overall concentration of proteins in biological systems, it may not reflect their actual activities, as protein activities depend not only on their concentrations, but also on post-translational modification(s), protein-protein interactions, binding of activators, repressors, or co-factors, or changes in tertiary structure. Therefore metabolomics, which directly measures these activities, brings a new dimension to our knowledge, helps to explain many regulatory events, and can map the complex relationships of individual molecules and pathways to predict cellular behavior and responses to various stimuli. Like the other OMICS techniques, the results of metabolomics strongly depend on the selected methodology. GC-MS and LC-MS approaches detect different classes of metabolites, and should be used as complementary techniques to increase metabolome coverage. Extraction methods can be used to decrease the complexity of the samples and focus on very specific molecules. Therefore, the choice of individual methods is the most critical aspect of metabolomics experimental design, and must be driven by biological questions. In summary, metabolomics represents a very valuable tool, however, careful selection of individual analytical and statistical steps is essential to understand the results and avoid their misinterpretation.

Metabolic Networks: A Background for Biomarkers

Network biology is a branch of science that deals with the interactions among biomolecules that include genes, transcripts, proteins, metabolites, etc. With the advent of system biology, networks are being used widely across many branches of biology (proteomics, genomics, transcriptomics, and metabolomics) as a convenient representation of the interaction between specific biological elements. These graphical representations denote the molecular-level blueprint of interactions and mechanisms of regulation inside a cell. These biological networks include gene regulatory network, transcriptomic network, protein–protein interaction network, and metabolic network. The network biology approach helped to cover the overall aspects of the necessary facets that need to be considered while finding the probable therapeutic intervention for the particular disease type. The interaction data come through the high-throughput methods that are gathered from individual studies and large-scale screens that finally get assembled into a topological form (i.e., network format) that holds significant biological properties. In a recent scenario, more attention has been given to the gene and protein networks to study a complex form of diseases (Shukla and Singh, 2017). Although it has been found that the metabolic networks seem to play a significant role in the complex disease regulation like in case of cancer's Warburg effect (Vander Heiden *et al.*, 2009), which signifies uncontrolled cell division even in anaerobic conditions that involve numerous metabolites and the reaction mechanisms. The metabolic network comprises of metabolites and enzymes that take the role of nodes and the reactions describing their transformations and is represented as directed edges in Fig. 1 (Bourqui *et al.*, 2007).

Biochemical reactions happening inside a metabolic network allow an organism to grow, reproduce, and respond to the environment and maintain its structure (Xu *et al.*, 2016). In a biochemical pathway, the metabolic network centralizes its attention towards mass flow that generates essential components like amino acids, sugars, and lipids, and the energy required by the biochemical reactions (Zhu *et al.*, 2007). In a metabolic network, it's not only metabolites that perform the overall metabolism but there are genes and proteins too that commence their task in regulatory mechanisms; this is what makes the metabolic networks more efficient from the disease perspective and their immediate applications too for therapeutic interventions (Berkhout *et al.*, 2013). This shows that metabolic networks typically show the representation of not only metabolites but also for genes and proteins and therefore provide wide perspective in disease studies. In a cell, metabolism holds chemical processes by which cells break down food and nutrients into usable building blocks and then reassemble those building blocks to form the biological molecules known as metabolites (DeBerardinis and Thompson, 2012). The metabolites consumed are called the substrates of the reaction; however those produced are called the products. Most metabolic reactions do not occur spontaneously, or we can say that they occur at a very low rate; therefore enzymes are used to enhance the pace of the reaction to get it completed (Cooper, 2000). This breakdown and reassembly in a pathway entails a set of successive chemical reactions that convert initial inputs into useful end products via a series of steps and this complete set of reactions in the pathway forms the metabolic network (Sridharan *et al.*, 2015). To understand the interacting mechanism in a network it's necessary to understand the architecture of the network topology. In a metabolic network, nodes represent the chemicals produced and consumed by the reactions that include small molecules (i.e. carbohydrates, lipids, amino acids, and nucleotides), and the edges denote the metabolic flow or the regulatory effects of a specific reaction (Lee *et al.*, 2008). Understanding the complex network often requires a bottom-up approach that carries its path towards systems biology perspective (Shahzad and Loor, 2012). Thus there is need to examine a system, not only in terms of individual components but as a whole, which can be done by considering the elementary constituents individually as well as when they are connected. Numerous components of a system and their interactions are best characterized as networks and they are mainly represented as graphs where thousands of nodes are connected with thousands of vertices (Cho *et al.*, 2012).

Fig. 1 Basic metabolic network.

Network analysis has suggested that biological networks have two imperative structural properties (Mahadevan and Palsson, 2005). First, it has been shown that several of these networks, including metabolic networks, are scale-free and possess a “small world” property (Barabasi and Oltvai, 2004). Second, scale-free networks are suggested to have high error tolerance and low attack tolerance (Crucitti *et al.*, 2004). In general, interactions in a network between biological entities (genes, transcripts, proteins, metabolites, etc.) can be classified on the basis of the nature of the interaction into two broad categories, i.e., influence networks and the flow networks. For influence networks, the nature of interactions are “influence-based” such as protein–protein interaction or signaling networks, i.e., connections mark the presence or absence of the reaction (Mahadevan and Palsson, 2005). This class might be extended with the case where the type of interaction is important in addition to presence or absence of the interaction, e.g., gene regulatory networks where transcription factors can either activate or repress gene expression. While in flow networks, where a specific variable like mass or energy flow may be conserved at each node, such as metabolic networks. However, it should be noted that the fundamental properties of biological networks in these two classes can be significantly different (Barabasi and Oltvai, 2004). It has been seen widely that along with the complete network graph, the subgraphs are also seen to play an essential functional role like network motifs (that represent most frequently occurring subgraph) and studies have shown the structural organization of the feedback loops (Fig. 2). Similarly, single-input and multiple-input motifs (Fig. 2) (Sehgal *et al.*, 2015) can influence the dynamics and the regulation of metabolic pathways (Beber *et al.*, 2012). For effective analysis it’s important to model the network graphs correctly for which there are a wide variety of approaches depending on the features of interest through which network dynamics can be modeled, like for small networks with explicit kinetics, which can be modeled with differential equations, while for larger networks dynamics can be accessed by flux balance analysis or stochastic kinetic modeling (Boccaletti *et al.*, 2006). Also, for the case where only stoichiometric information is available, more basic approaches like network expansion or Petri nets can be utilized (Peleg *et al.*, 2005).

Varieties of graph representations are available in network biology but studies have shown that bipartite graph (Fig. 3) (two nodes represent metabolites with edges joining each metabolite to the reaction) is the most correct representation of the metabolic network (Veeramani and Bader, 2010). The edges in the representative graphs are directed because some metabolites (the substrates) go into the reaction and some (the products) come out of it. Metabolic networks are represented through nodes as metabolites and the links as reactions that are catalyzed by specific gene products; this representation is different from protein–protein interaction networks, where the nodes are the gene products and the links correspond to interactions. The analysis of protein–protein interaction networks has suggested that the deletion of the most highly connected proteins correlates well with a lethal phenotype (Mahadevan and Palsson, 2005). In contrast, a node in metabolic networks cannot be deleted by genetic techniques, but links can (Jeong *et al.*, 2001).

Now the question comes as to how the resultant computational network are formed and how their global representation is possible. The answer lies in the computer readable file formats for the biological networks, i.e., Systems Biology Markup Language (SBML), a global format which could be utilized for the reusability of network models. It is a XML-like machine-readable language that is proficient to represent models to be analyzed by a computer. SBML can represent metabolic networks, cell signaling pathways, regulatory networks, and many other kinds of systems (Hucka *et al.*, 2003). An increasing number of diseases are now

Fig. 2 Most frequent regulatory motif.

Fig. 3 Bipartite graph with corresponding simple representation.

seen to be a result of drastic perturbations of cellular functions that involve large sets of genes, where connections are complicated to understand. Diseases in particular like cancer, CVD, or diabetes causes huge perturbations in cell metabolism. Therefore, the study of metabolic networks primary perturbation in interactions and fluxes can aid better understanding of the physiopathology of such diseases. It notably permits an understanding of how and why alteration in activity or expression levels of a few enzymes can transmit substantial perturbations into entire cellular functions. Therefore these metabolites could have been proposed as putative biomarkers for the human diseases.

Metabolome Analysis: Computational Protocols and Methods

The metabolome comprises of the biochemical composition of the small-molecule metabolites present in a cell that are involved in the metabolic reaction mechanism and required for the maintenance, growth, and normal functioning of the cell (Mohny and Milburn, 2015). The metabolome was first described by Oliver and colleagues in 1998 (Oliver *et al.*, 1998), during their pioneering work on yeast metabolism that therefore confers the discipline of metabolomics; that follows the analysis of the metabolome. Metabolomics is sometimes also called metabonomics or metabolic profiling (Lindon *et al.*, 2011). Various experimental, statistical, and computational approaches have been discovered so far to perform the metabolome analysis. The most commonly used experimental techniques in metabolomics are mass spectrometry (MS), i.e., gas chromatography (GC-MS) or liquid chromatography (LC-MS), and nuclear magnetic resonance spectroscopy (NMR) spectra (Zhang *et al.*, 2012). Along with this statistical approaches have been devised to perform the analysis and it comprises of various standard analysis methods such as t-test and ANOVA, as well as more sophisticated methodologies such as univariate and multivariate analysis methods (Bartel *et al.*, 2013).

Also, bioinformatic approaches fall into the scenario due to the boom in high-throughput data and this includes databases for the data retrieval as well as web servers for carrying out the analysis (Maudsley *et al.*, 2011). Tremendous efforts have been implemented to archive all types of biological data, i.e., genes, proteins, gene products, metabolites, etc. With the advent of the genomic era, the amount of biochemical knowledge has exploded in the last two decades, which has necessitated its storage in large databases. Variety of top-down (gene to protein to metabolite) and bottom-up (chemical entity to biological function) approaches have been implied resulting in a rich expanse of metabolic knowledge from the biochemical network (Cakir and Khatibipour, 2014). Bioinformatics is a pioneer in preserving the data obtained through the experimental or natural resources and also provided the numerous tools for the analysis purpose. The databases provide the contextual biochemical basis for metabolomics data interpretation. By providing information regarding metabolites like defining which enzymatic reactions consume or produce them, and which pathways they're involved in, researchers can use this data to interpret their experiments towards a higher level of annotation.

METLIN, was the first metabolomics database, was established in 2004 (Smith *et al.*, 2005). Thereby in 2005, the Human Metabolome Project was launched to find and catalog all of the metabolites in human tissue and biofluids. This metabolite information is kept in the Human Metabolome Database, which produced its first draft in 2007 (Wishart *et al.*, 2007). There are many databases containing metabolomics data, and each has different information, ranging from NMR and MS spectra to metabolic pathways. Additionally, and more specifically to the development of metabolomics, mass spectral databases like the Golm Metabolome Database (Hummel *et al.*, 2007), which links mass spectrum and chromatographic retention time to specific compounds, have been developed. Some tools designed for higher level metabolomic analysis can take GC-MS spectra as input and use them for the identification stages of metabolomics. The purpose of metabolic databases is to organize the metabolites in a way that helps researchers in an easy identification and analysis. The information found in metabolite databases has continuously been updated to provide state-of-the-art data to the scientific community. Metabolomics is a new field and therefore new approaches are still being discovered and the existing ones are still improving. These databases are embraced with various types of information including concentration, anatomical location, and related disorders.

Other databases are MassBank (Horai *et al.*, 2008), lipid metabolites and pathways strategy (LIPID-MAPS) (LIPID), Madison metabolomics consortium database, and Kyoto Encyclopedia of Genes and Genomes (KEGG) (Kanehisa and Goto, 2000). The major database till now is the KEGG, which is divided into several subdatabases with LIGAND, REACTION PAIR and PATHWAY being the most relevant to metabolomics (Booth *et al.*, 2013). In KEGG however there is a dauntingly large sum, i.e., 10,664 reactions and 18,107 metabolites (Kanehisa and Goto, 2000). These databases have been undergoing continuous updation and annotation for and so contain a great deal of valuable information. KEGG and MetaCyc (Karp *et al.*, 2002) are currently the largest (most number of organisms) and most in-depth comprehensive databases available. There are other databases too as Reactome (Joshi-Tope *et al.*, 2005), Model SEED (Devoid *et al.*, 2013), and BiGG (Schellenberger *et al.*, 2010), that can be more useful than the large databases if a specific organism is desired. The KEGG and MetaCyc databases each contain a generalized conserved set of pathways based on metabolic pathways. For KEGG, organism-specific annotations are available to query while for MetaCyc, individual "Cyc" databases have been generated for a number of organisms, some are just computationally derived while others are extensively manually curated such as AraCyc for *Arabidopsis* (Mueller *et al.*, 2003) and EcoCyc for *E.coli* strain K-12 MG1655 (Karp *et al.*, 2014). A more recent development is the cheminformatic databases like PubChem (Wang *et al.*, 2009) and ChEBI (Degtyarenko *et al.*, 2007), which provide a chemically ontological approach to catalog small molecules that are active in biological systems. These databases, therefore, can provide fruitful information regarding the metabolic datasets. Finally, it is important to note that these databases can be cross-referenced and linked to each other as well as against more widely known databases such as the well-known Chemical Abstract Service (CAS) among many others. Along with the above mentioned

Table 1 Selected databases and tools w.r.t metabolomics

<i>Databases</i>		
BioCyc	Collection of 10992 Pathway/Genome Databases (PGDBs)	http://biocyc.org
BiGG Models	Knowledgebase of genome-scale metabolic network reconstructions.	http://bigg.ucsd.edu/
BMRB	Repository for data from nuclear magnetic resonance spectroscopy (NMR) spectroscopy on proteins, peptides, nucleic acids, and other biomolecules	http://www.bmrw.wisc.edu/
BRENDA	Comprehensive enzyme repository, provide metabolic pathway details	http://www.brenda-enzymes.info/index.php
CHEBI	Freely available dictionary of molecular entities focused on “small” chemical compounds	https://www.ebi.ac.uk/chebi/
DIMEdB	Database of biologically relevant metabolite structures and annotations	http://dimedb.ifers.aber.ac.uk/
DRUGBANK	Unique bioinformatics and cheminformatics resource that combines detailed drug (i.e., chemical, pharmacological, and pharmaceutical) data with comprehensive drug target (i.e., sequence, structure, and pathway) information	https://www.drugbank.ca/
ECMDB	Contains extensive metabolomic data and metabolic pathway diagrams about <i>Escherichia coli</i> (strain K12, MG1655)	http://ecmdb.ca/
GMD	Facilitates the search for and dissemination of reference mass spectra from biologically active metabolites quantified using gas chromatography coupled to mass spectrometry (MS)	http://gmd.mpimp-golm.mpg.de/
HMDB	Archive information about small-molecule metabolites found in the human body	http://www.hmdb.ca/
KEGG	Resource for understanding high-level functions and utilities of the biological system, such as the cell, the organism and the ecosystem, from molecular-level information	http://www.genome.jp/kegg/pathway.html
MANET	Maps evolutionary relationships of molecule (metabolic, protein) architectures directly onto biological networks	http://manet.illinois.edu/
MassBank	Contains high resolution mass spectral data	http://massbank.eu/MassBank/
MetaboLights	Database for metabolomics experiments and derived information	http://www.ebi.ac.uk/metabolights/
MetaNetX	Automated model construction and genome annotation for large-scale metabolic networks	http://www.metanetx.org/
Reactome	Navigable map of human biological pathways, ranging from metabolic processes to hormonal signaling	http://www.reactome.org
SMPDB	Support pathway elucidation and pathway discovery in metabolomics, transcriptomics, proteomics and systems biology	http://smpdb.ca/
YMDB	Manually curated database of small-molecule metabolites found in or produced by <i>Saccharomyces cerevisiae</i>	http://www.ymdb.ca/
<i>Computational analysis tools</i>		
Arcadia	Visualization tool for metabolic pathways	http://arcadiapathways.sourceforge.net/
CellNetAnalyzer	MATLAB toolbox providing a various (partially unique) computational methods and algorithms for exploring structural and functional properties of metabolic, signaling, and regulatory networks	http://www.mpi-magdeburg.mpg.de/projects/cna/cna.html
GLAMM	Unified web interface for visualizing metabolic networks, reconstructing metabolic networks from annotated genome data, visualizing experimental data in the context of metabolic networks, and investigating the construction of novel, transgenic pathways	http://glamm.lbl.gov/
IMPALA	Perform pathway overrepresentation and enrichment analysis with expression and/or metabolite data	http://impala.molgen.mpg.de
iPath	Web-based tool for the visualization, analysis and customization of the various pathways maps	http://pathways.embl.de
JDesigner	Graphical modeling environment for biochemical reaction networks	http://jdesigner.sourceforge.net/Site/JDesigner.html
KaPPA-View	Web-based analysis tool for integration of transcript and metabolite data on plant metabolic pathway	http://kpv.kazusa.or.jp/en/
LIPID MAPS	Online tools for lipid research	http://www.lipidmaps.org/tools/index.html
MapMan	A user-driven tool to display genomics data sets onto diagrams of metabolic pathways and other biological processes	http://mapman.gabipd.org/web/guest/mapman
MetaMapp	Mapping and visualizing metabolomic data by integrating information from biochemical pathways and chemical and mass spectral similarity	http://uranus.fiehnlab.ucdavis.edu:8080/MetaMapp/homePage
MetPA	A web-based metabolomics tool for pathway analysis and visualization	http://metpa.metabolomics.ca
MassTRIX	Annotate metabolites in high precision MS data	http://masstrix3.helmholtz-muenchen.de/masstrix3/
MetaboAnalyst	Web server designed to permit comprehensive metabolomic data analysis, visualization and interpretation	http://www.metaboanalyst.ca/MetaboAnalyst/
MetaPath Online	For the analysis of metabolic networks	https://scopes.biologie.hu-berlin.de/

(Continued)

Table 1 Continued

<i>Databases</i>		
Meta P-server	A web based, easy-to-use analysis tool for the statistical analysis of metabolomics data	http://metabolomics.helmholtz-muenchen.de/metap2/
MetExplore	Find information about metabolite relationships in metabolic networks	http://metexplore.toulouse.inra.fr/metexplore/
Metscape	A plug-in for Cytoscape, used to visualize and interpret metabolomic data in the context of human metabolic networks	http://metscape.ncibi.org
MGV	A versatile generic graph viewer for multiomics data also it offers a comprehensive set of tools for analysis and visualization of graphs.	http://www.microarray-analysis.org/mayday
MPEA	Metabolite pathway enrichment analysis	http://ekhidna.biocenter.helsinki.fi/poxo/mpea/
MSEA	A web-based tool to identify biologically meaningful patterns in quantitative metabolomic data	http://www.msea.ca
Omix	Network drawing tool along with programmable visualization framework	http://www.omix-visualization.com/?from=http://www.13cflux.net/#sthash.vLyVKteK.dpbs
Paintomics	A web based tool for the joint visualization of transcriptomics and metabolomics data	http://www.paintomics.org
TICL	A web tool for network-based interpretation of compound lists inferred by high-throughput metabolomics	http://mips.helmholtz-muenchen.de/proj/cmp/home.html
Vanted	Network visualization and analysis tool for creating and editing the network and mapping experimental data onto networks	https://immersive-analytics.infotech.monash.edu/vanted/

Table 2 PAM50 genes list

<i>PAM50 genes</i>				
ACTR3B	CDCA1 (NUF2)	FOXA1	MDM2	PGR
ANLN	CDH3	FOXC1	MELK	PHGDH
BAG1	CENPF	GPR160	MIA	PTTG1
BCL2	CEP55	GRB7	MKI67	RRM2
BIRC5	CXXC5	KIF2C	MLPH	SFRP1
BLVRA	EGFR	KNTC2(NDC80)	MMP11	SLC39A6
CCNB1	ERBB2	KRT14	MYBL2	TMEM45B
CCNE1	ESR1	KRT17	MYC	TYMS
CDC20	EXO1	KRT5	NAT1	UBE2C
CDC6	FGFR4	MAPT	ORC6L(ORC6)	UBE2T

databases there are different types of databases built so far only the selected ones based upon accuracy and applications are mentioned in alphabetical order in [Table 1](#).

Similarly, there are many computational tools available for the metabolic data handling like for building, editing, enrichment, and interpreting metabolic network models, including Arcadia ([Villegier et al., 2010](#)), GLAMM ([Bates et al., 2011](#)), CellNetAnalyzer ([Klamt and von Kamp, 2011](#)), MetaMapp ([Barupal et al., 2012](#)), MetPA ([Xia and Wishart, 2010a](#)), Vanted ([Rohn et al., 2012](#)) for network visualization. Likewise there are tools for drawing a network, Omix ([Droste et al., 2013](#)) which have been widely used for creating a network model. TICL ([Antonov et al., 2009](#)) is used for the interpretation of compound lists that are inferred by high-throughput metabolomics. Enrichment analysis could be done with the help of MSEA ([Xia and Wishart, 2010b](#)), MPEA ([Kankainen et al., 2011](#)). MassTRIX ([Suhre and Schmitt-Kopplin, 2008](#)) performs the annotating metabolites in high precision MS data. There are other tools also, which have been mentioned in [Table 2](#) along with their descriptions.

Biomarker Discovery: A Challenge and Plausible Solutions Through Bioinformatics

Biomarkers are measured indicators of biological and pathogenic conditions or pharmacological responses to a therapeutic intervention ([Strimbu and Tavel, 2010](#)). Based on pathophysiological, epidemiological, therapeutic, or other scientific evidence they are intended to be useful in terms of clinical significance (i.e., to know whether they will benefit or harm) ([Baumgartner et al., 2011](#); [Downing, 2001](#)). Biomarkers have a generous impact on the care of patients; for those who are suspected to have the disease or those who have or have no visible disease symptoms ([Baumgartner et al., 2011](#)). For a long time biomarkers have served as a plausible diagnostic key to unraveling disease conditions, especially in case of cancers. Depending on the condition type they can be categorized as diagnostic, prognostic, and screening biomarkers ([Madu and Lu, 2010](#)). Currently, screening biomarkers are of high interest due to their ability to predict future events, but there are only a few accepted biomarkers for disease screening available today ([Melander et al., 2009](#)). Therefore it is necessary to have considerable search, verification, biological and

biochemical interpretation, and independent validation of disease biomarkers, which requires advancement in high-throughput technologies. To achieve this goal there is necessity to have interdisciplinary expertise, which requires the teamwork of clinicians, biologists, biochemists, and bioinformaticians to carry out biomarker cohort studies with professional planning, implementation, and control. Bioinformatics plays a key role in the biomarker discovery process via bridging the gap between initial discovery phases such as experimental design, clinical study execution, and bioanalytics, including sample preparation, separation, high-throughput profiling, and independent validation of identified candidate biomarkers (Baumgartner *et al.*, 2011) (Fig. 4).

It is well known that a disease or a phenotype is rarely a consequence of an abnormality of a single gene or its expression but instead reflects the interactions of various processes in a complex network; such network could combine multiple genes (proteins) and metabolites. For example, plants can produce numerous metabolites to handle different environmental conditions however the biosynthetic pathways for most of these compounds have not yet been revealed (Schlapfer *et al.*, 2017). From these facts, the need for a disease signature, a set of compounds generally presented as a network, becomes evident. Such disease-specific signature could be helpful in understanding all its mechanisms and evolution and in an earlier diagnosis. Multiple works and frameworks aimed to either use genes expression or metabolic data to extract a set of disease-relevant compounds; it's safe to say biomarkers (Strimbu and Tavel, 2010). Identifying such crucial biomarkers responsible for disease characteristics and revealing its mechanisms can be used to infer its evolution and development and offers better targets for drug development, treatment individualization, and dose regimen. These biomarkers are selected by analytic methods or pathway and network-centric methods (Wang *et al.*, 2015). A typical case would be gene expression data of two pairs of samples in both disease and normal states help in discovering genes and metabolites which can be potential biomarkers (Li *et al.*, 2013; Shlomi, 2010; Li *et al.*, 2012). Cancer is a heterogeneous disease, for instance, breast cancer. Biomarkers at the DNA, RNA, and protein levels were developed to better understand the biology of breast cancer, leading to the possibility to classify the disease into subtypes and subgroups, which may lead to new therapeutic opportunities (Le Du *et al.*, 2013). Many tests are available for the diagnosis and each one is based on a set of genes; we can list some of most known ones such as PAM50. PAM50 stands for Prediction Analysis of Microarray 50 (Sweeney *et al.*, 2014), fifty genes were probed like *ACTR3B*, *ANLN*, *BAG1*, *BCL2*, *BIRC5*, etc. Elaborating a set of biomarkers allowed the development of many tools online (cbioportal (Gao *et al.*, 2013)) and offline, in libraries and packages. These tools offer the possibility of analyzing targeted datasets and understanding the disease stage. Machine learning tools are also a very effective way of dealing with such complex diseases, predicting treatment effectiveness and new treated disease trajectory. Since these, new models have been well designed, which fully explains the relationship between each biomarker.

Fig. 4 Computational pipeline for metabolome analysis.

Gene Expression and Metabolic Network: Applications in Biomarker Discovery for Complex Diseases

DNA microarray technologies permit systematic approaches to the biological discovery that have a profound impact on biological research, pharmacology, and medicine (Yousef *et al.*, 2014). The ability to obtain quantitative information from the complete transcription profile of cells provides a powerful means to explore basic biology, disease diagnosis, drug development, mold therapeutics to specific pathologies, and generate databases (Young, 2000). Gene expression studies bridge the gap between DNA information and its trait information by dissecting the biochemical pathways into intermediate components, that is, between genotype and phenotype (Xiong *et al.*, 2001). The gene expression studies, therefore, open new avenues for identifying complex disease genes and biomarkers for disease diagnosis and also for assessing drug efficacy and toxicity. One particularly powerful application of gene expression analyses is in biomarker discovery, which can be used for disease risk assessment, early detection, prognosis, predicting response to therapy, and preventive measures.

For years, scientists studied one gene at a time and genes were indeed studied in isolation from the larger context of other involved genes. Nowadays, genomics via high-throughput techniques helps to study the genome of organisms as a whole thus allowing a wide picture of gene characteristics. One of the most popular high-throughput techniques are arrays, which are an orderly arrangement of a large number of samples allowing large-scale studies (Yousef *et al.*, 2014). This gave rise to the genomic era, which emerged from the sequencing of genomes from many organisms. The development of the first arrays started many years ago to study a large number of genes at a time (Hergenhahn *et al.*, 2003) and has widely expanded since then. Today the approach is also applicable to RNA probes, proteins, antibodies, and even biological samples allowing new types of research (Yousef *et al.*, 2014). Currently, other types of high-throughput techniques are also developing, for instance, to study the transcripts and metabolites.

Today, genomics has induced two new paradigms in biology; the first paradigm is a new approach that allows the study of the complex network through which genes and proteins communicate. It is attained via an amalgamation of the researcher having expertise in the field of biology, engineering, chemistry, and computer science; this multidisciplinary approach allows the development of systems biology. The second paradigm is a direct consequence of information derived from genomics studies where raw data needs to be analyzed and then to be used in the systemic approach. This led the development of bioinformatics,

Fig. 5 Network interaction of the PAM50 genes set.

which requires the use of computers to manage biological information. The practical applications of gene expression analyses are numerous and only beginning to be realized. One particularly powerful application of gene expression analyses is in biomarker identification, which can be used for disease risk assessment, early detection, prognosis, prediction response to therapy, and preventative measures.

Therefore approaches to cancer biomarker discovery comprise genomics, epigenomics, transcriptomics, and proteomic analyses. Current efforts in the laboratory focus on the identification of biomarkers in chronic lymphocytic leukemia, lung cancer, and colon cancer (McDermott *et al.*, 2013). Along with the mRNA other small RNAs are also known to be a predictive indicator in disease studies; and it has been found that alterations in gene expression patterns due to dysregulation of miRNAs is a common cause in tumorigenesis (Chen *et al.*, 2012). High concentrations of cell-free miRNAs that originate from the primary tumor have been found in the plasma of cancer patients, and several lines of evidence indicate that plasma miRNAs are associated with specific vesicles called exosomes (Yang *et al.*, 2016). This led to the discovery of new biomarkers that comprises plasma miRNAs and seems to be promising in disease prognosis (Jeffrey, 2008). Recent discovery of quantifiable circulating cancer-associated miRNAs exposes the immense potential of their use as novel minimally invasive biomarkers for breast and other cancers (Heneghan *et al.*, 2009).

Discovery of Biomarkers Through Computational Pipeline: A Cancer Based Study

The classification of samples from gene expression datasets usually involves a small number of samples. The problem of selecting those biomarker genes that are vital for differentiating the different sample classes being compared poses a challenging problem in

Fig. 6 Oncoprint for only four biomarkers.

Fig. 7 Survival study.

case of the high dimensional data analysis. A variety of methods to address this problem have been implemented and these methods can be divided into two main categories: (1) Filtering based methods and (2) model-based or wrapper approaches (Wang *et al.*, 2005; Inza *et al.*, 2004). The filter method (Ben-Bassat, 1982) assesses the goodness of the proposed feature subset looking only at the intrinsic characteristics of the data, based on the relation of each single gene with the class label by the calculation of simple statistics computed from the empirical distribution. This approach is extensively used as a feature subset selection method in the microarray (Aris and Recce, 2002). While in the wrapper approach (Kohavi and John, 1997), which is a very powerful machine learning application, search is conducted in the space of genes, evaluating the goodness of each found gene subset by the estimation of the accuracy percentage of the specific classifier to be used.

One of the most important properties that should be considered for the biomarkers is the robustness. It is an important issue for the successful discovery of biomarkers, as it may greatly influence subsequent biological validations. In addition, a more robust set of markers may strengthen the confidence of an expert in the results of a selection method (Abeel *et al.*, 2010). Robustness, a property that allows a system to maintain its functions under certain external and internal perturbations, is a ubiquitously observed feature of biological systems (Kitano, 2004). Studying the relationship between the topology and robustness of

Fig. 8 Breast cancer histogram with subtypes.

metabolic networks may help to understand the functional organization principle of cells and could have important implications for disease studies (Schuster and Holzhütter, 1995) and drug target identifications (Bakker *et al.*, 2000).

The robustness of the metabolic network with respect to specific enzymes can be qualitatively estimated by the preservation or decay of the network after removal of the nodes or edges corresponding to these enzymes. The following topological features of metabolic networks may ensure the robustness of metabolism; these are (1) modularity, which contributes to the robustness of networks by decreasing the cross talk between different functional modules, detaining perturbations and damages to separable parts and preventing deleterious effects from spreading to the whole system (Stelling *et al.*, 2004); (2) bow-tie structure, which aids in forming a robust conserved core because it is the most tightly connected part of the network and there are multiple routes between any pair of nodes. Such connecting patterns provide an advantage in generating a coordinated response to various stimuli and increases the robustness of the whole system (Kitano, 2004); and (3) scale-free topology; the key feature of scale-free networks is the high-degree of error tolerance; that is, the ability of their nodes to communicate is unaffected by the failure of some randomly chosen nodes (Crucitti *et al.*, 2004). Thus the scale-free nature of metabolic networks indicates its high resistance towards random perturbations and thus could explain why some enzyme dysfunction at the metabolic level is without substantial phenotypic effect (Barabasi and Albert, 1999). The studies have shown that the scale-free networks are extremely vulnerable to attacks, i.e., the removal of a few hub nodes that play a crucial role in maintaining a network's connectivity will destroy the whole network (Crucitti *et al.*, 2004). Studies conducted by Mahadevan and Palsson showed that low-degree nodes are almost as likely to be critical to the overall network functions as high-degree nodes (Mahadevan and Palsson, 2005) by calculating the number of lethal reactions among all the reactions connected to every metabolite in the substrate graph of metabolic networks.

To show an example of analysis using biomarkers a dataset from (Pereira *et al.*, 2016) was used. It presents a somatic mutation profiling study of 2433 breast cancers, which approved the classification of the tumors into 10 integrative clusters (IntClusters).

Fig. 9 Coexpression of two biomarkers, ACTR3B & GPM6B.

During this study (Pereira *et al.*, 2016) CNAs (copy number aberrations) were the main driver in an unsupervised clustering approach due to their influence on genes expression. The current analysis used the dataset above against the fifty genes found in PAM50 (Table 2). These genes served as a gene set for the cBioportal, so the mutations profiling could be performed. Figures below show different knowledges extracted, cancer types, and mutation happening along genes, genes with similar or exclusive expression, and finally survival estimation. Gene networks present an excellent input for models analysis using algorithmic methods such as Bayesian networks, leading to inferring and predicting the cancer evolution, trajectory, and progression (Caravagna *et al.*, 2016). Fig. 5 shows the interaction of the PAM50 gene set where nodes are representing genes and edges (arrows) denote the interactions between them.

Thereby an oncoprint of four biomarkers (TMEM45B, TYMS, UBE2C, UBE2T) has been captured (Fig. 6) that shows the type of mutation occurring to the gene set.

After this, a survival study has been conducted (Fig. 7), which is performed for the p-value of 1.164e-5 and red color denotes the alteration in query gene while blue color shows the query gene without alteration. It has been noticed that the cases with alterations have higher survival rate than the nonaltered ones.

Then alteration frequency of ACTR3B and ANLN were determined through the histogram (Fig. 8) that denotes the alteration and the deletion frequency. Finally Pearson and Spearmen correlation coefficient induced shows the coexpression of the two biomarkers, that is, ACTR3B & GPM6B (Fig. 9).

Concluding Remarks

The advent of high-throughput technologies, and as a result, the generation of various kinds of omics data, has challenged both the experimental or computational scientific communities. Therefore an “omics cascade” came into the scenario where the genotype to the phenotype can be connected through various intermediate steps for better understanding the disease biology and their overall impact on the phenotypic observations at the physical or organism level. Understanding the genotype to phenotype scenario and its consequences will provide an edge towards better implementation of computational methods for their experimental validations. It will be an added advantage for the scientific community to amalgamate the computational and experimental procedures for the betterment of mankind. It is anticipated that this comprehensive text will provide systematic and ordered information on the metabolic world with its exact connection to the biomarker identification procedure.

Introduction

Living cells generate energy and produce building material for cell components and replenish enzymes by the process of metabolism. All organisms live and grow by receiving food and nutrients from the environment. The foods are processed through thousands of reactions. In cells chemical reactions take place round the clock constantly breaking and making chemical molecules and transferring ions and electrons and these reactions are called metabolic pathways. Therefore, the metabolites can be considered as the preliminary level molecules generated from food intakes which are gradually transformed into building blocks for producing proteins, RNAs and DNAs and other useful matter and energy for creating and maintaining cells and life.

Metabolic reactions follow the laws of physics and chemistry and thus modeling metabolic reactions require considering many physicochemical constraints (Palsson, 2006). Metabolic pathways are efficiently regulated to respond to external perturbations and internal needs and thus linked to signaling networks. Many severe human diseases are caused by metabolic imbalance e.g., diabetes, cancer, cardiovascular problems, obesity, gout, tyrosinemia are a few to name.

Metabolism is the general term for the following two kinds of reactions: (i) Catabolic reactions: Catabolism refers to chemical reactions that result in the breakdown of more complex organic molecules into simpler substances. Catabolic reactions usually release energy that is used to drive chemical reactions. In catabolism, large molecules such as polysaccharides, lipids, nucleic acids and proteins are broken down into smaller units such as monosaccharides, fatty acids, nucleotides, and amino acids. The energy of catabolic reactions is used to drive anabolic reactions. (ii) Anabolic reactions: Anabolism refers to chemical reactions in which simpler substances are combined to form more complex molecules. Anabolic reactions usually require energy. Anabolic reactions build new molecules and/or store energy. The energy for chemical reactions is stored in ATP.

The term metabolic network usually means a collection of metabolic reactions represented as networks where the metabolites are the nodes and two metabolites are connected if one of them is a substrate and the other is the product of a reaction. Genome scale reconstruction of a metabolic network involves thousands of metabolites and reactions. Metabolic reactions are catalyzed by enzymes. The enzymes are gene products or proteins in broader sense. Therefore, metabolic networks contain information about both metabolites and proteins where the metabolites are nodes and proteins/enzymes are edges. There are other ways of representing metabolic pathways such as Bipartite graphs and Petri nets (Koch *et al.*, 2004; Matsuno *et al.*, 2011). A Petri net is an attributed directed bipartite graph. A metabolic pathway can be represented as a bipartite graph by considering the metabolites as one set of nodes and the enzymes as another set of nodes and such representation can provide some overall preliminary information about the system. Other than the metabolic pathways, we can also construct different type of metabolic networks e.g., based on structural similarity or any other type of similarity between metabolites.

Some studies showed that the metabolic networks are scale free networks i.e., their degree distribution follows power law (Jeong *et al.*, 2000; Ma and Zeng, 2003). Above all metabolic networks can be regarded as small world networks for their power-law degree distribution, high clustering coefficient and low average path length and diameter (Strogatz, 2001; Fell and Wagner, 2000). High clustering coefficients imply the existence of modules in the networks. It has been proposed that the combined properties of power-law degree distribution and high clustering coefficient indicates that the modules in the networks are linked to one another in a hierarchical manner (Albert *et al.*, 2000).

Numerous and versatile researches have been conducted based on pathways and chemical structures of metabolites. In this book article, we focus somewhat detail on two research topics. In the first part of this article we discuss alkaloid synthesis pathways and in the second part of this article we discuss structural similarity based networks of metabolites and its usage in establishing structure activity relations.

Insight Into Alkaloid Synthesis Pathways

Metabolites can be broadly classified into two types, primary metabolites and secondary metabolites. Primary metabolites are involved in normal growth, development, and reproduction of an organism and are usually present in almost all organisms. On the other hand, secondary metabolites are not generally essential for the very survival of an organism but mainly have important ecological functions. Usually, secondary metabolites are present in taxonomically restricted groups of organisms such as plants, fungi, bacteria etc. The term 'secondary' was introduced in 1891 (Kossel, 1891) in the context of metabolites. The functions of secondary metabolites are acquired in evolution process involving pest and pathogen defense, UV-B-sunscreens (Dixon, 2001) etc. Secondary metabolites with known chemical structures are more than 3000 terpenoids, 9000 flavonoids, 1600 isoflavonoids and 12,000 alkaloids (Connolly and Hill, 1991; Ziegler and Facchini, 2008). Since 2004, we have been accumulating the relations between metabolites and producing species in KNApSACk Core Database (DB, see "Relevant Websites section"), presently which

are 102,005 species-metabolite relationships encompassing 20,741 species and 50,054 metabolites. It has been predicted based on current statistics of metabolites-species relations, that there are at least 1.06 million metabolites within all plants on this planet of which most are secondary metabolites (Afendi *et al.*, 2011).

The classification of secondary metabolites based on integrated information of chemical structure and metabolic pathways could provide important clues to activities of metabolites which lead to interpretation of function acquisition mechanisms of secondary metabolites in evolutionary process. In this part of the article, we examine whether or not classification of alkaloids by ring skeletons can be related to metabolic pathways. Alkaloids are a large group of nitrogen-containing secondary metabolites. Almost every variety of organisms such as bacteria, fungi, plants, and animals produce alkaloids. Diverged polycyclic compounds including unsaturated and saturated bonds are produced by various organisms (Fig. 1 shows some examples).

Systematic representation of alkaloid biosynthetic pathways has been established by Aniszewski based on ring skeletons. The skeleton nucleus of an alkaloid is the main criterion for alkaloid precursor determination in biosynthetic pathways. Skeletons for different alkaloid nuclei can be produced by L-lysine, for example, piperidine, indolizine, quinolizidine nuclei are respectively represented by skeletons C5N, C5NC3 and C5NC4 (Tadeusz, 2007). Here C5N means a skeleton with 6-membered ring including 1 nitrogen atom, C5NC3 means the heterocyclic ring skeleton composed by 6-membered ring including 1 nitrogen atom together with 5-membered ring including 1 nitrogen, and C5NC4 means the heterocyclic ring skeleton composed by 6-membered ring including 1 nitrogen atom together with 6-membered ring including 1 nitrogen. C5NC and C5NC4 contains common C-N bonds in two heterocyclic systems. As shown in Fig. 1, the synthetic pathways of quinolizidine alkaloids from L-Lysine (L-Lys) to Lupanine (C2) and Multiflorine (C3) and to Lycodine (C6), three compounds C1, C2, and C3 have identical ring skeleton S1, whereas, C4 has the skeleton S2, and C5 and C6 have the skeleton S3. Here ring skeleton is defined as ring structures without saturated or unsaturated chemical bonds. Thus, classification of alkaloids based on ring skeletons can provide important information for systematic understanding of chemical structures and for predicting biosynthetic pathways. Here, we discuss structure-based classification of secondary metabolites as a multidisciplinary field combining chemo- and bio-informatics.

Data Set

Information of 478 polycyclic compounds were accumulated whose metabolic pathways were available in references. We collected pathway information from scientific literatures and constructed 32 pathway maps (Eguchi *et al.*, 2017). The summary of these 32 pathway maps is depicted in Table 1. We made alkaloid pathway maps considering starting compounds as amino acids, compounds related with amino acid biosynthesis (anthranilate, formyl anthranilate, indole-3-glycerol phosphate, O-methyl tyrosine) terpenes, compounds related with TCA cycle and fatty acids and nucleic acids because alkaloids are often divided into the true alkaloids which originate from amino acids and pseudoalkaloids that do not originate from amino acids, for example, terpene-like, steroid-like and purine-like alkaloids.

Subring Skeleton Profiling

Fig. 2 shows the subring skeleton profiling with the example of benzoisoquinoline alkaloid biosynthetic pathway from L-Tyr to Sanguinarine (C13). Out of 7 compounds (C7–C13), C12 and C13 have the same ring skeleton S9 and the others have separate ring skeletons (S4–S8). Next, subring skeletons were produced for individual skeletons (S4–S9). For example, S4 corresponds to nine subring skeletons (SRSs) (A–I in Step 1 of **Fig. 2**). SRS matrix *S* was constructed by setting $s_{ij} = 1$ or 0 respectively depending on presence or absence of the *j*th SRS in the *i*th compound (Step 2). Here we used InChI (the IUPAC International Chemical Identifier) for isomorphism check for SRSs (Heller *et al.*, 2015; Spjuth *et al.*, 2013). In Step 3, hierarchical clustering of the compounds was performed using matrix *S*. There are several molecular fingerprint techniques such as PubChem (881 bits) (Bolton *et al.*, 2008), CDK (1024 bits) (Steinbeck *et al.*, 2003), Extended CDK (1024 bits) (Durant *et al.*, 2002), MACCS (166 bits) (Klekota and Roth, 2008), Klekota–Roth (4860 bits) (PubChem Substructure Fingerprint, see “Relevant Websites section”), Substructure (307 bits) (Person VUE see “Relevant Websites section”), Estate (79 bits) (Minato, 1993), and atom pairs (780 bits) (Iwashita *et al.*, 2012). Those molecular finger prints generally focuses on side-chain substructures of molecules. Alternatively, SRS profiling makes it possible to examine and compare compounds based on all possible SRS, so SRS profiling is useful for systematic understanding of the evolution process of ring systems of the compounds.

Subring Skeleton Profiling in Alkaloids

We extracted 2546 unique subring skeletons from 478 compounds. **Fig. 3** shows the distribution of the numbers of compounds along with the number of SRSs. It is interesting that there is no unique SRS in 478 compounds, that is, there is no SRS corresponding to only one compound.

Secondly, we represented each compound as a 2546 dimensional binary vector. Here, if *i*th subring skeleton is present in a target compound, the *i*th element was set to 1; otherwise, the *i*th element was set to 0. We applied ward clustering method to a matrix consisting of 478 compounds and 2546 unique SRSs and allocated 478 compounds into 29 clusters (Cluster ID = 1 to 29) as shown by the dendrogram in **Fig. 4**. All compounds were assigned to 187 ring skeletons which have been presented in Eguchi *et al.* (2017).

Fig. 2 Schematic diagram of subring skeleton (SRS) profiling.

Fig. 3 Distribution of the number of SRSs along with number of compounds.

We divided the compounds into 6 major groups labelled as G1 (Clusters 1 and 2), G2 (Cluster 3), G3 (Cluster 4), G4 (Clusters 5–7), G5 (Clusters 8) and G6 (Cluster 9–29) as shown in [Fig. 4](#); G1 and G2 are related with indole-diterpenes involving paxilline, terpendoles and lolitrems (G1) and strictosides (G2). These consist of polycyclic compounds comprised of six to nine rings characterized by 5–6 member rings and only one nitrogen; Compounds in G3 (Cluster 4) are related with steroidal alkaloids with

Fig. 4 Dendrogram of 478 compounds based on SRS profiling.

glucosides including alpha-solanine, alpha-chaconine, and alpha-tomatine and their skeletal chemical structures are assigned with steroidal alkaloids; compounds included in G4 (Clusters 5–7) are characterized by vindoline derivatives with greater than or equal to 2 nitrogen atoms; G5 corresponds to Ergot alkaloids. The other alkaloid compounds belong to G6 (Clusters 9–29) and also have very diverged ring skeletons. Clusters 9–20 can be characterized as follows; aglycones and glucosides of Tomatidines (Clusters 9 and 10, respectively), bis-isoquinolines (Cluster 11), morphinans (Cluster 12), quinazoline derivatives (Cluster 13), indolizidine derivatives (Cluster 14), polynuridines (Cluster 15), Ajmalicines (Cluster 16), Berberine and relatives (Clusters 17–19). Ipecac alkaloids (Cluster 20), isoquinolines including ring skeletons of glaudines (Cluster 21), beta-carbolines (Cluster 22), chaetoglobosin (Cluster 23), ring skeletons roquefortines and acetylazonaleins (Cluster 24), Emindoles (Cluster 25), quinolizidines (Cluster 26), iboganines (Cluster 28), and communesins (Cluster 29). Thus the 28 clusters except cluster 27 can be characterized by ring skeletons based on the sub-ring skeleton profiles proposed by [Eguchi et al. \(2017\)](#).

Almost half of the compounds (233 compounds) examined in this study belong to Cluster 27. So we further divide it into 25 sub-clusters to characterize ring skeletons as representatives of groups of compounds. The 25 sub-clusters in Cluster 27 are composed of relatively simple heterocyclic ring skeletons in comparison to other clusters. Five sub-clusters (A, B, C, D, E, F, and H) have indole type alkaloid structures based on ring skeletons, and especially characterized by brevianamides (A); cyclopiazonate derivatives (B) and chanoclavin derivatives, that is, the former corresponds to a five-cyclic ergot alkaloids and the latter corresponds to tri-cyclic ergot alkaloids; chimonanthines (E); and iboga alkaloids (H). Furthermore, specific ring skeletons can be observed in individual sub-clusters such as, ergolines (B and C), cinchona alkaloids (G), iboga alkaloids (H and I), lycopodium alkaloids (J and K), isoquinolines (L), lupine alkaloids (M), quinolones (N), quinolones (O), acridines and quinolones (P), purine alkaloids (Q), and benzyloquinoline alkaloids (T). In summary the conclusion is, alkaloid compounds can be classified and characterized according to generally defined ring systems based on subring skeleton profiles.

Relations Between Ring Structure and Pathways

We classified alkaloid compounds based on subring skeleton profiles and thus related general ring structures to groups of alkaloids. Next, we tried to find associations between modules in alkaloid metabolic pathways and ring structures. We mapped compounds onto 32 pathway maps and show in [Table 2](#) the summary of the relations between classification results and pathway maps. All but four clusters (Clusters 13, 22, 24, 25 and 27) correspond to single pathway maps (PMs). Thus, clusters expressed by the subring skeleton profiles are highly associated to alkaloid biosynthetic pathways. Such trends are also observed in case of the sub-clusters in Cluster 27 (10 out of 25 sub-clusters). Details of the relations between pathway maps and ring structures have been presented in [Eguchi et al. \(2017\)](#).

Structure Activity Relationship Based on Network of Metabolites

Organisms acquired selective functions through evolution to drive functional specialization together with retaining underlying enzymatic genes. Evolutionary pressures caused the appearance of different secondary metabolites and related pathways. These metabolites are important for healthy survival, e.g., pest and pathogen defense and UV-B sunscreens ([Dixon, 2001](#)). The aroma of black Périgord truffle, *T. melanosporum* is produced by secondary metabolism which is used to attract animals for sporulation ([Islam et al., 2013](#)). Thus, plant

secondary metabolites are compounds of diverse types of structures and serve as defense weapons used against bacteria, fungi, amoebae, plants, insects, and herbivorous animals and as agents of symbiosis between microbes and plants, nematodes, insects, and higher animals and also as pheromones and pollinators. Secondary metabolites help an organism maintain various interactions with the eco-systems, often adapting to match the environmental needs. Secondary metabolites of plants that color the plant or plant parts e.g., flowers are a good example of this, as the coloring of a flower can attract pollinators and also certain coloring of leaves or stems can defend against attack by animals. Volatile organic compounds (VOCs) are special type of metabolites. VOCs emitted by bacteria and fungi might have the potential to be alternatives to chemical pesticides to protect plants from pests and pathogens. Microbial VOCs are seen as biocontrol agents to control various phytopathogens and as biofertilizers for plant growth promotion. Furthermore, metabolites are deeply involved in human health care. The use of VOCs as biomarkers to detect human diseases is rapidly increasing. Plant metabolites are a major sources of drugs and they are widely used in pharmaceutical industries.

In order to systematize the relations between secondary metabolites and biological activities and to facilitate a comprehensive understanding of the relationships between the chemical structure of metabolites and their biological activities, we developed a metabolite-activity relation database known as the KNApSACk Metabolite Activity DB (see “Relevant Websites section”) (Nakamura *et al.*, 2014). Here, we present a network-based approach to systematically understand the relationship between 3D-chemical structures of metabolites and their biological activities (Ohtana *et al.*, 2014). We initially constructed a 3D-chemical structure similarity based network of secondary metabolites and then applied DPCLUSO (Altaf-Ul-Amin *et al.*, 2006, 2012) algorithm to extract densely connected clusters (referred to as structure groups) of metabolites. We then statistically validated the relationship between the structure groups and biological activities and selected significant structure group-biological activity pairs using a threshold p -value. The p -value threshold was decided based on false discovery rate (FDR) to address the problems associated with multiple testing (Benjamini and Hochberg, 1995). Finally, we reconstructed a binary matrix consisting of selected structure groups and biological activities. Hierarchical clustering was then applied to the constructed matrix in order to detect global trends of relations between 3D structures and biological activities.

The Proposed Method to Assess Structure-Activity Relationships

The concept of the proposed method is depicted in Fig. 5 and the details of the individual steps are described below.

In Step 1, a network was constructed where a node represents a metabolite and an edge represents high 3D structural similarity between metabolites. Fast heuristic graph match algorithm COMPLIG (Saito *et al.*, 2012) was utilized to estimate structural similarity between metabolites at the 3D level. COMPLIG calculates structure similarity based on three factors namely, topology-distance, bond-order, and rotatable-bond and has been previously utilized for systematically classifying ligands in PDB (Saito *et al.*, 2012). We estimated similarity score $S(A, B)$ between two metabolites A and B using the following equations:

$$S(A, B) = M(A, B) / \max\{N(A), N(B)\}$$

Here, $M(A, B)$ is the number of atoms and bonds matched between metabolites A and B , and $N(A)$ and $N(B)$ are the number of atoms and bonds in metabolites A and B , respectively. We considered 0.80 as the threshold similarity which was recommended by Saito *et al.* (2012). Thus, structurally similar metabolites were connected with each other to construct a network of metabolites.

In Step 2, we used a network-clustering algorithm DPCLUSO to classify metabolites into highly structurally similar groups. DPCLUSO generates clusters characterized by high density and separated by periphery in the networks (Altaf-Ul-Amin *et al.*, 2006, 2012), and has been used in several big data analyses in molecular biology such as protein-protein interaction (Altaf-Ul-Amin *et al.*, 2006), metabolomics (Takahashi *et al.*, 2008) and prediction of functional relations between genes using gene expression (Altaf-Ul-Amin *et al.*, 2014).

In Step 3, we annotated structure groups by biological activities using chi-square statistic χ^2 and an over-representation test statistic OV (Kanaya and Kudo, 1994) defined as follows:

$$\chi^2 = \frac{(c(x, k) - f(k) \cdot T)^2}{f(k) \cdot T} + \frac{(c(x, \bar{k}) - f(\bar{k}) \cdot T)^2}{f(\bar{k}) \cdot T}$$

$$OV = \frac{c(x, k) - f(k) \cdot T}{\sqrt{f(k) \cdot T}}$$

Here, $c(x, k)$ and $c(x, \bar{k})$ represent the number of metabolites with and without the k th activity in structure group x , $f(k)$ and $f(\bar{k})$ represent relative numbers of metabolites with and without the k th activity in the database, T represents the total number of metabolites in the structure group x . It is evident that the degree of freedom is 1 for the χ^2 value represented above.

A structure group can have significant p -values in χ^2 -statistics either if it is overrepresented or underrepresented by metabolites of certain biological activity in the context of the ratio of the metabolites in the DB. However, our purpose is to relate a structure group to a biological activity if and only if the structure group is overrepresented by metabolites associated with that biological activity. Therefore, we first make sure that the OV statistic is positive for a structure group and then we evaluate its p -value.

In Step 4, we construct a data matrix based on the statistically significant relation between structure groups and biological activities, and carried out 2-dimensional hierarchical clustering for systematizing the relationship between metabolite structures and biological activities.

Selection of Statistically Significant Relationships Based on False Discovery Rate

We examined 3D-similarities among 2072 secondary metabolites by a fast heuristic graph-matching algorithm COMPLIG developed by Shirai and colleagues (Saito *et al.*, 2012) and then 50,228 pairs of secondary metabolites having similarity score more than the threshold were selected to construct a network. Then structure groups were generated using the graph clustering algorithm DPCLUSO (Altaf-Ul-Amin *et al.*, 2012) which was developed for overlapping clustering using the similar concepts of the DPCLUS algorithm (Altaf-Ul-Amin *et al.*, 2006). DPCLUSO generated 671 densely connected clusters of secondary metabolites, which are called structure groups (SGs) in this study.

We searched for statistically significant relationships between 671 SGs and 140 biological activities (Table 3). The biological activities are of mainly two types: (i) Chemical ecology related activities indicated as E01–E48 in Table 3 which are associated with metabolites involved in ecological interactions between species for survival and normal regulation of organisms, and (ii) human healthcare and medicine related activities indicated as M01–M92 which are associated to metabolites known as ingredients of healthy foods and medicines or biomarkers.

Fig. 5 Concept of the methodology: network construction based on 3D-structure similarity between metabolites. Nodes and edges represent metabolites and highly similar pairs of metabolites, respectively. Different colors in Step 3 represent different biological activities for individual metabolites. In Step 4, 2D-hierarchical clustering is carried out based on statistically significant relations between structure groups and biological activities. Red colors represent significant relation between corresponding structure group and biological activity.

We first selected 7650 structure group-biological activity pairs (SG-BA pairs) for which *OV* is positive to ensure over-representation of metabolites of the activity category in the associated cluster. We then examined FDR (cumulative *q*-values) using *p*-values calculated based on χ^2 -statistics, and finally selected 983 SG-BA pairs which correspond to $p < 0.001$ and $q < 7.78 \times 10^{-3}$.

Relation Between Structure and Biological Activities

Multiple activities are generally reported for a metabolite, for example, (+)-catechin has been reported to have several biological activities in chemical ecology (e.g., E18, E20 and E32 in [Table 3](#)) and in human healthcare and medicine (e.g. M29, M34, M39,

Table 3 Biological activities defined in the KNApSack Metabolite Activity DB

General description	Activity category
Plant growth regulator	Enhance germination (E01), Enhance stem growth (E02), Enhance root growth (E03), Enhance leaf growth (E04), Enhance flowering (E05), Enhance fruiting (E06), Enhance plant growth (E07), Inhibit seed germination (E08), Inhibit stem growth (E09), Inhibit root growth (E10), Inhibit leaf growth (E11), Inhibit flowering (E12), Inhibit fruiting (E13), Inhibit plant growth (E14), Allelopathic (E15), Phytoalexin (E16)
Attractant/repellent	Feeding attractant (E17), Feeding deterrent (E18), Pollinator attractant (E19), Oviposition attractant (E20), Oviposition deterrent (E21), Sex attractant (E22), Attractant (E23), Repellent (E24)
Selective toxicity	Phytotoxic (E25), Herbicidal (E26), Insecticidal (E27), Acaricidal (E28), Molluscicidal (E29), Piscicidal (E30), Nematocidal (E31)
Antimicrobial agent	Antibacterial (E32), Antituberculosis (E33), Antileprotic (E34), Antifungal (E35), Inhibit spore germination (E36), Antimicrobial (E37)
Antiviral agent	Antiviral (E38), Antihepatitic (E39), Anti-HIV (E40), Anti-HSV (E41)
Antiparasitic agent	Anthelmintic (E42), Antiprotozoal (E43), Antiamebic (E44), Antimalarial (E45), Antileishmanial (E46), Antitrypanosomal (E47), Pediculicide (E48)
Nervous system agent	Antipyretic (M01), Analgesic (M02), Antiarthritic (M03), Anesthetics (M04), Sedative (M05), Antispasmodic (M06), Anticonvulsant (M07), Antidementic (M08), Antidepressant (M09), CNS Stimulant (M10), Diaphoretic (M11), Emetic (M12), Antiemetic (M13), Antigout (M14), Antimigraine (M15), Antimyasthenic (M16), Antiparkinson (M17), Antipsychotic (M18), Muscle relaxant (M19)
Cardiovascular agent	Antidiabetic (M20), Hemostatic (M21), Antithrombotic (M22), Cardiotonic (M23), Antiarrhythmic (M24), Diuretic (M25), Antihypertensive (M26), Antihyperlipidemic (M27), Antianemic (M28), Other cardiovascular agent (M29)
Respiratory tract agent	Antitussive (M30), Expectorant (M31), Antiasthmatic (M32), Other respiratory tract agent (M33)
Digestive organ agent	Antidiarrheic (M34), Carminative (M35), Stomachic (M36), Laxative (M37), Choloretic (M38), Antihepatotoxic (M39), Other digestive organ agent (M40)
Genitourinary agent	Oxytocic (M41), Antifertility (M42), Abortifacient (M43), Other genitourinary agent (M44)
Anticancer agent	Antioxidant (M45), Anticancer (M46), Antitumor (M47), Antineoplastic (M48), Antimutagenic (M49)
Anti-inflammatory agent	Anti-inflammatory (M50), Antiallergic (M51), UV shield (M52), Antidermatitic (M53), Antiedemic (M54)
Immunological agent	Immunosuppressant (M55), Immunostimulant (M56), Immunomodulator (M57)
Nutrient	Nucleic acid (M58), Essential amino acid (M59), Nonessential amino acid (M60), Vitamin (M61), Nutrient (M62), Tonic (M63)
Nontherapeutic agent	Solvent (M64), Flavor (M65), Odor (M66), Pigment (M67), Emulsifying agent (M68), Antiseptic (M69)
Other health agent	Antilulcerogenic (M70), Depilatory (M71), Antidote (M72), Hormonal (M73), Dental (M74), Other health agent (M75)
Narcotic	Narcotic (M76)
Toxic	Phototoxic (M77), Neurotoxic (M78), Pneumotoxic (M79), Hepatotoxic (M80), Cytotoxic (M81), Toxic (M82)
Tumorigenic	Tumorigenic (M83), Mutagenic (M84), Genotoxic (M85), Teratogenic (M86)
Other disease-causing agent	Psychotomimetic (M87), Hemolytic (M88), Allergenic (M89), Irritant (M90), Dermatitic (M91), Edematous (M92)

M40, M45, M48, M70, M81, M82, M88 and M91 in [Table 3](#)) which are easily retrieved by entering “(+)-catechin” as Metabolite Name in the Metabolite Activity DB ([Nakamura et al., 2014](#)). To systematically understand the relations between biological activities and structure groups, we constructed a 2-dimensional dendrogram, using a matrix showing relations among 488 structure groups and 139 activities.

[Fig. 6](#) presents the relationship between SGs and biological activities in the perspective of hierarchical clustering. We tentatively distributed 139 biological activities into 13 clusters called BC1 to BC13. Relationships between major biological activities that are connected with 10 or more structure groups are listed in [Table 4](#). It should be noted that activity categories in three clusters (BC1, BC2 and BC3) described as antimicrobial agent and plant growth regulator are related to ecology and six clusters (BC4, BC5, BC7, BC10, BC11 and BC13) are associated with human healthcare. On the other hand, three clusters (BC6, BC9 and BC12) are related to both ecology and healthcare activities.

To examine the relationship between chemical structures and biological activities, we selected SGs that are related to single activity category ([Table 3](#) shows the list of activity categories) and assigned chemical structural properties into individual SGs (SG-ID in [Tables 4](#) and [5](#), SG-ID 389 is abbreviated as SG389 and so on in the following text). Three clusters of major metabolites namely isoflavonoids (BC1), flavones and isoflavones (BC2) and giberrellanes (BC3) were assigned as ecological activity agents. BC1 exhibits antifungal properties (E35) whereas BC2 contained phytoalexins (E16) and BC3 are characterized as plant growth regulators with properties such as stem growth enhancement (E02), plant growth enhancement (E07) and root growth inhibition (E10). BC6 mainly consists of phenolic substances with both ecological and healthcare activities, i.e. anthraquinones (SG113), coumarins (SG236 and SG237) flavones (SG147), phenylpropanoids (SG327 and SG404) as antibacterial agents (E32), and lignans (SG43, SG75, SG82, SG278 and SG376) as antitumor agents (M47), and stilbenoids (SG147) as antibacterial agents (E32). Flavonoids including isoflavonoids have diverse functions as both ecological and healthcare agents because most of the bioactivity groups (BC1, BC2, BC4, BC5, BC6, BC9 and BC12) include various structural derivatives and thus specific functions can be exerted by patterns of substitution groups in the chemical structures. Ecological activities of these metabolites are highly related with core chemical structures most likely because these metabolite groups characterize certain biosynthetic pathways. This leads to

Fig. 6 2D-hierarchical clustering (Ward's method) between metabolite groups (vertical direction) and biological activities (horizontal direction). The whole map (A) and enlarged views (B) and (C). Index numbers in horizontal clustering represent cluster ID.

the explanation that the role of metabolites in plant physiological activities is highly related with evolution of biosynthetic pathways in plants.

SGs listed in the healthcare category of [Table 4](#) correspond to single activities but the extent of their effects in plants has not been fully understood. Efficacies in humans of many SGs consisting of alkaloids can be mentioned: BC5, isoquinoline alkaloids (SG217) as analgesic agents (M02), quinoline alkaloids (SG430) as sedatives (M05), terpene alkaloids (SG152 and SG220) as antihypertensivity agents (M26); BC6, indole alkaloids (SG651) with antitumor properties (M47); BC7, quinolizidine alkaloids (SG489) and terpene alkaloids (SG112 and SG267) with toxicity properties (M82); BC9, betalains (SG172, SG289, SG419, SG420, SG438, SG439 and SG497) as pigments (M67); BC11, steroid alkaloids (SG461) as laxatives (M37); BC13, pyrrolizidine alkaloids (SG320 and SG479) and quinolizidine alkaloids (SG429) as antidiabetic agents (M20), tropane alkaloids (SG578), and indole alkaloids (SG649) with hormonal properties (M73), quinoline alkaloids (SG261 and SG298) as phototoxic agents (M77), isoquinoline alkaloids (SG361, SG447 and SG644) and indole alkaloids (SG202 and SG317) with psychotomimetic properties (M87).

Alkaloids occur in 20% of all plants and the number of identified structures are more than 12,000 ([Connolly and Hill, 1991](#); [Ziegler and Facchini, 2008](#)). Initially in the 1950s, most of these alkaloids were believed to be metabolic waste products ([Wink et al., 1998](#)). Currently biological activities of alkaloids found in nature have been determined and the medical effects of alkaloids to humans are well known. Those include toxicity to animals, vertebrates and arthropods, effects of various metabolic systems in animals, inhibiting DNA synthesis and repair by intercalation with nucleic acids, and other reported effects on the nervous systems ([Mithöfer and Boland, 2012](#)). Specific healthcare activities can also be explained by class of metabolites,

especially class of alkaloids listed in Tables 4 and 5. Comparative activity relationships between ecological and healthcare agents lead to systematization of meta-metabolomics combined with human and ecological metabolic pathways (Raes and Bork, 2008; Ibrahim and Anishetty, 2012). As an example the structure group 55 (Fig. 7(A)) is significantly related with multiple biological activities, that is, plant growth regulators such as enhancing stem growth (E02), enhancing leaf growth (E04), and enhancing plant growth (E07), and consists of 21 metabolites which are highly related with gibberellin and its relatives. Another example, structure group 362 (Fig. 7(B)) is associated with the following healthcare activities: sedative (M05), analgesic (M02), anti-spasmodic (M06) under the general description nervous system agent, antitussive (M30) under respiratory tract agent; narcotic (M76) under narcotic; and antidiarrheic (M34) under digestive organ agent. The core structure in group 362 can be identified as morphinoids.

Table 5 Structure properties for SGs in Table 2. The number of metabolites in SG is represented in parentheses

BC	Structure properties	SG-ID
1	Coumestrols	389(5)
	Isoflavonoids	36(30), 68(18), 78(16), 250(7), 270(7)
2	Anthraquinones	8(55), 16(47)
	Flavones	7(56), 8(55), 11(51), 14(50), 16(47), 17(46), 22(40), 25(37), 27(37), 49(24), 70(18), 186(9), 269(7)
	Flavanols	27(37)
	Flavanones	8(55), 85(16), 279(7)
	Flavonoids	33(33), 64(19)
	Isoflavanones	71(18), 115(13)
	Isoflavones	11(51), 16(47), 27(37), 71(18), 115(13)
	Lignans	71(18), 115(13)
	Pterocarpanes	93(15)
3	Gibberellanes	392(5), 510(3), 594(3)
	Triholosides	511(3)
4	Biflavonoids	409(5)
	Cymenes	575(3)
	Furans	624(3)
	Glucosinolates	319(6)
	Nonalactones	349(5)
	Phenols	230(7)
	Phenylpropanoids	97(15), 469(4)
5	Coumarins	366(5)
	Isoquinoline alkaloids	217(8)
	Quinoline alkaloids	430(5)
	Terpene alkaloids	152(10), 220(8)
6	Anthraquinones	113(13)
	Coumarins	236(7), 237(7), 601(3)
	Sesquiterpenes	331(5), 354(5)
	Flavones	147(11)
	Indole alkaloids	651(5)
	Lignans	43(26), 75(17), 82(16), 278(7), 376(5)
	Phenylpropanoids	327(6), 404(5)
	Sesquiterpenes	460(4)
	Stilbenoids	147(11)
7	Cibarians	523(3)
	Cyanogenic glycosides	239(7), 373(5), 488(4)
	Heterodendrins	411(5)
	Quinolizidine alkaloids	489(4)
	Terpene alkaloids	112(13), 267(7)
9	Anthocyanins	574(3)
	Anthraquinones Betalains	40(27)
	Betalains	172(9), 289(6), 419(5), 420(5), 438(4), 439(4), 497(4)

Conclusions

Bioinformatics and Cheminformatics play important roles in interpretation and understanding chemical and biological data. Two of the major targets of Big Data science are to advance human health care and to understand ecosystems based on huge distributed data. Secondary metabolites are used by humans for various purposes and they play important roles in ecological relationships between species. The evolutionary history and broad functional spectrum of secondary metabolites is still not fully understood. In the present book article, we discuss two research topics, first is on alkaloid synthesis pathways and the other is on structure activity relationships of metabolites. In the first study we utilized the subring skeleton (SRS) profiles to systematize alkaloids into groups and to relate individual compounds and groups to metabolic pathways. Applying clustering method to SRS profiles, the variety of ring skeletons across 29 clusters and 25 subclusters was clearly understood. Systematization of core cyclic structure, biological activity and biosynthetic pathway of metabolites can provide new insight into interpretation of evolution process for active compounds in nature. The second topic is on a methodology for the integrated interpretation of the relationships between chemical structures and biological activities based on network clustering algorithm and taking into consideration statistics controlled by false discovery rate. Given the importance of metabolites in agriculture, ecology and healthcare it would be of great help to various sectors of science and technology to predict the functions of the function-unknown metabolites by using some computational means based on their chemical structures. Natural product chemistry associated with metabolomics will shift towards the data-intensive sciences and needs to simultaneously integrate and examine different types of data such as chemical structure and biological activity for new discoveries and development of novel drugs interacted with proteins and the identification of viable drug resources and other useful compounds. Techniques and approaches discussed in this article provide clues to comprehensive understanding of evolution of metabolic pathways and structure-activity relationships in the context of metabolites.

Glossary

Active site It is an asymmetric pocket, present on or near the surface of a biomolecule, that promotes chemical catalysis upon binding of appropriate substrate.

Alignment Method for comparing two or more sequences/structures to assess the overall similarity.

Base stacking Aromatic rings of DNA or RNA bases lie on top of each other.

Coiled-coils These structures are formed when two or more α -helices wind around each other to give a supercoil. The constituent helices may either run in the same (parallel) or in the opposite (anti-parallel) directions.

Domain A compact unit of protein structure that can fold on its own and have independent function.

Electrostatic interactions The non-covalent interaction between oppositely charged atoms or groups of atoms.

Homology modelling A computational method for modelling the structure of a biomolecule based on its sequence similarity to one or more biomolecules of known structure.

Motif It can be either sequence or structure motif.

Sequence motifs have recognizable amino-acid sequences found in different proteins. Structural motifs are segments of protein 3D structure that is formed by the spatially close residues. These residues may or may not be adjacent in the sequence.

RNA-thermometer RNA-thermometer, also known as RNA-thermosensor, is a temperature sensitive non-coding RNA molecule that regulates gene expression.

Super-secondary structure Super-secondary structures are combination of secondary structures and can be considered as an intermediate between secondary and tertiary structures. α -hairpins, β -hairpins and β - α - β motifs are commonly found super-secondary structures.

Van der Waals interaction These are weak attractive forces between two atoms or groups of atoms that arise due to the fluctuations in electron distribution around the nuclei. Van der Waals forces are stronger between less electronegative atoms.

Central Dogma of Life

According to the classical view, also known as Crick's central dogma, "the coded genetic information hard-wired into DNA is transcribed into individual transportable cassettes, composed of messenger RNA (mRNA); each mRNA cassette contains the program for synthesis of a particular protein (or small number of proteins)" (Lodish *et al.*, 2000) (Fig. 1). Though all biological cells adhere to this rule, there are few notable exceptions as well (Birney *et al.*, 2007; Gerstein *et al.*, 2007). Over-simplification of this rule can allow us to make a statement: "DNA makes RNA and RNA makes proteins" and involves two distinct steps, namely transcription and translation. RNA polymerase along with transcription factors transfers the information coded in DNA to messenger RNA and the process is known as transcription. Translation process facilitates the sequence encoded in the RNA molecule to get decoded into an amino acid sequence which defines a protein. DNA must make identical copies of itself to pass on the genetic information from parent to offspring. DNA polymerase and its associated proteins make possible this phenomenon, known as replication. These events are highly dependent on the 3D structures of DNA/RNA as well as associated proteins. In this article, we will discuss various structural elements of DNA, RNA and proteins. We will also highlight different algorithms for their prediction, identification and analyses, with emphasis on more recent reports.

Base-Pairing and Double Helical Structure of DNA

The double helical structure of DNA, as proposed by Watson and Crick in 1953 (shown schematically in Fig. 2(A)), revolutionized our understanding of biology at the molecular level (Watson and Crick, 1953). The model had two strands entwining around a common helical axis and linked together by a specific Hydrogen-bond (H-bond) scheme (Fig. 2(B)) that plays a major role in stabilizing the nucleic acid structures. The canonical Watson-Crick DNA structure has right handed screw sense with the two chains in anti-parallel orientations and 10 nucleotides per turn. The separation among two consecutive bases in a chain is 3.4 Å along the helix axis (Fig. 2(A)). In general, there are two types of H-bonding in nucleic acid structures (1) Watson-Crick (WC) and (2) non-Watson-Crick (NWC). In the canonical Watson-Crick scheme two H-bonds occur between the Adenosine and the Thymine base-pairs (bps), while there are three such bonds between the Cytosine and the Guanine (Fig. 2(B)). The specificity of this base-pairing scheme is the key to conservative replication of DNA and the transmission of exact information from one generation to the next. However, the large number of nucleic acid structures determined by x-ray diffraction and available in various databases, such as Nucleic Acid Database (NDB; see Relevant Website section)

Fig. 1 Schematic representing the Central Dogma of Life.

(Coimbatore Narayanan *et al.*, 2014) and Protein Data Bank (PDB) (Berman *et al.*, 2000) has revealed a wide variety of structures and their conformational adaptability. In addition, a number of different types of non-WC base-pairing with two H-bonds have been observed (Fig. 3) (Lu and Olson, 2008).

DNA and RNA Can Adopt Different Structural Forms

Change in environment play a significant role on twisting, turning and stretching the structure of DNA leading to different forms of DNA (Bansal, 1999); described A-Z forms of DNA, with the exception of the letters F, Q, U, V and Y (Ghosh and Bansal, 2003). Among these helical forms, Watson-Crick model for B-DNA is the most commonly known. There are two other well-known type of helices: A-form and Z-form (Table 1). A-DNA was first observed by Franklin and Gosling in 1953 when they got the X-ray pattern recorded for fibres of the sodium salt of calf thymus DNA under low humidity (Franklin and Gosling, 1953). RNA double helices also have a structure similar to A-DNA (Rich and Davies, 1956). Z-DNA has two nucleotides in a repeating units and a left-handed screw sense. In general, it has alternating purine (Guanine) and pyrimidine (Cytosine) sequences with alternating sugar puckers as well as syn/anti conformations about the glycosyl bond (Wang *et al.*, 1979). Other forms of DNA are described elsewhere (Ghosh and Bansal, 2003).

Like DNA, each RNA strand contains nitrogenous bases covalently bound to a sugar-phosphate backbone. However, RNA is usually single-stranded and the sugar is ribose instead of deoxyribose as in DNA. It also contains Uracil in place of Thymine base. RNA molecules, usually, have a single-stranded structure that can fold over to form different secondary structures viz. hairpin loops, bulge loops, internal loops or multi loops. These loops are stabilized by intra-molecular H-bonds between complementary bases that are important for their functions as well as stability (Holley *et al.*, 1965). In general, RNA secondary structure can have four basic elements namely helices, loops, bulges, and junctions. Stem-loop or hairpin loop is the most common element of RNA secondary structure (Tinoco and Bustamante, 1999) and consists of a stem and a loop. Stem is formed when the RNA chain folds back to form a double helical tract and the unpaired nucleotides form a single stranded loop. Hairpins with loop length of four nucleotides are quite common and also known as tetraloops. Sequences of these tetraloops form three major clusters: UNCG, GNRA, and CUUG (N is one of the four nucleotides and R is a purine) with UNCG being the most stable (Hollyfield *et al.*, 1976). The unpaired nucleotides in one strand of a double helix produce bulge in that strand. However, if the bulge is present in both the strands, it is referred to as an internal loop (Fig. 4). Internal loops can be symmetric or asymmetric depending on the number of nucleotides in each bulge. Two hairpins or internal loops with single stranded RNA often interact with each other to produce pseudoknots, identified for the first time in the turnip yellow mosaic virus (Rietveld *et al.*, 1982). Pseudoknots are found to have catalytic activities (Staple and Butcher, 2005).

In the year 1960, the first experimental demonstration of DNA-RNA hybrid double helix paved the way for understanding the transfer of information from DNA to RNA (Rich, 1960). Currently, there are more than 100 DNA-RNA hybrid and chimera structures available in NDB.

Apart from double helices, DNA and RNA can form triplexes as well as quadruplexes. Triplexes are of two types namely (1) minor groove triplex and (2) major groove triplex. The minor groove triplex is found in almost all large RNAs (Devi *et al.*, 2015). The beet western yellow virus pseudoknot structure has a loop that forms a minor-groove triplex motif with a double

Fig. 2 (A) A schematic diagram of the Watson-Crick double helix. The base pairs are represented by horizontal bars and the sugar-phosphate backbones of the two chains, related by a twofold rotation axis perpendicular to the helix, are represented by ribbons running in opposite directions. The 5' and 3' ends are labelled for the ascending strand. The helix axis, its pitch and diameter and the major and the minor grooves have been identified. (B) Base pairs G · C and A · T with Watson-Crick and A · T with Hoogsteen hydrogen-bond schemes are shown as line diagrams. The base atoms are numbered according to the standard nomenclature and the hydrogen bonds between them are represented by dotted lines. The C1'–C1' distance and the C1'–C1'–N1/N9 angles are indicated in each case. The minor-groove and major-groove sides of the Watson-Crick base pair is indicated in the case of the A · T base pair. Reproduced with permission of the International Union of Crystallography. Available at: <https://journals.iucr.org/services/termsofuse.html>.

helical stem via 2'-OH and triple-base interactions (Su *et al.*, 1999). Minor groove triplexes allow a stable packing of loop and helix that make them critical in the structure of large ribonucleotides including group I intron (Szewczak *et al.*, 1998), group II intron (Boudvillain *et al.*, 2000) and the ribosome. In RNAs, major groove triplexes are not as common as their minor groove counterparts as the major groove in RNA double helices is narrow. However, triplex in B-DNA is possible via the formation of Hoogsteen or reversed Hoogsteen H-bonds in the major groove (Jain *et al.*, 2008).

Quadruplexes are higher order nucleic acid structures that are generally formed by G-rich sequences (Gellert *et al.*, 1962). Hoogsteen type H-bonds allow four Guanine bases to associate and form a square planar structure, a Guanine quartet, that stack on top of each other to give a G-quadruplex. The presence of Alkali ions in the central channel between each pair of tetrads adds to their stability (Largy *et al.*, 2016). Eukaryotic telomeres which are characterized by periodically repeating G-tracts (Sundquist and Klug, 1989; Wright *et al.*, 1997), are associated with quadruplex structures. However, they are also found in non-telomeric genomic DNA. Quadruplexes can be formed from one, two or four separate strands of nucleic acid and depending on the number of strands they can have a wide range of topologies (Burge *et al.*, 2006; Rhodes and Lipps, 2015) (Fig. 5). Depending on the topology and number of constituent strands, there is a variation in the consensus sequence as well (Burge *et al.*, 2006). Quadruplexes can be formed by triplet repeats like GAA, CCG, or CAG (Khateb *et al.*, 2004; Matsugami *et al.*, 2003). A statistical survey of short sequences that can form quadruplex in the human genome have identified few commonly occurring sequences like CCTGTCA, CCTGTT, CCTGTC and CCTGTTA (Todd *et al.*, 2005). It has also been shown

Fig. 3 Possible base pairing schemes between the bases. Adenine, Guanine, Uracil (Thymine), and Cytosine in their cononical (keto- and amino-) tautomeric forms and involving at least two H-bonds. A total of 28 base pairs including the two canonical WC pairs are possible. The reverse A · T/U and G · C WC pairs are asymmetric, and are numbered XXI and XXII respectively. Figure adopted from (with permission). Available at: <http://x3dna.org/highlights/reverse-watson-crick-base-pairs>.

Table 1 Comparison of various parameters of A-, B- and Z-DNA

Parameters	A-DNA	B-DNA	Z-DNA
Helix sense	Right-handed	Right-handed	Left-handed
Repeating unit	1 bp	1 bp	2 bp
Mean twist/bp (°)	+ 32.7	+ 36.0	− 60/2
Mean number of bp/turn	11	10	12
Mean Rise/bp along axis (Å)	2.6	3.4	3.7
Pitch of helix (Å)	28.6	34.0	44.4
Major Groove	Narrow and deep	Wide and deep	Flat
Minor groove	Wide and shallow	Narrow and deep	Narrow and deep
Glycosyl torsion angle	Anti	Anti	Pyrimidine: anti, Purine: syn
Nucleotide phosphate to phosphate distance (Å)	5.9	7.0	Pyrimidine: 5.7, Purine: 6.1
Sugar ring pucker	C3'-endo	C2'-endo	Pyrimidine: C2'-endo, Purine: C3'-endo
Helix Diameter (Å)	23	20	18

Fig. 4 Pictorial representation of primary, secondary, tertiary and quaternary structure of nucleic acid. PDB ID: 1EQZ and 4R4V are taken as representative examples of quaternary structures.

that the number of nucleotides in the loop, length of G-quartet and cations affect the formation and stability of duplex DNA vs quadruplexes (Cevcec and Plavec, 2005; Risitano and Fox, 2004). In early 2001, quadruplexes were described as “structures in search of a function” (Simonsson, 2001). However, several experiments have now shown their functional importance (Maizels and Gray, 2013; Rhodes and Lipps, 2015). G-quadruplex-forming DNA motif has been reported to be important in predicting the position of DNA replication origins in human cells (Besnard *et al.*, 2012). G-quadruplexes are known to protect the ends of telomere as well as regulate their length (Rice and Skordalakes, 2016). Biological insights along with the bioinformatics analyses of quadruplexes has paved the path for the discovery of drugs targeting them (Fernando *et al.*, 2009; Hänsel-Hertsch *et al.*, 2017; Xu *et al.*, 2017).

Intercalated motifs or i-Motifs are another type of quadruplexes that are formed from Cytosine rich sequences by intercalation and hemi-protonated cytosine–cytosine base-pairing (Gehring *et al.*, 1993). These sequences were found to occur in gene promoter regions and that may allow them to play a pivotal role in gene transcription (Guéron and Leroy, 2000). Hence, targeting them with ligand can provide novel methods for targeting genetic diseases (Day *et al.*, 2014; Sheng *et al.*, 2017). These motifs are not observed in RNA as there will be a repulsion between 2'-OH of ribose sugar (Lacroix *et al.*, 1996). The experimental validation of the formation of i-motifs can be done by experimental methods like NMR studies, X-ray crystallography, UV molecular absorption, molecular fluorescence based techniques, fluorescence resonance energy transfer, fluorescence correlation spectroscopy, time-resolved transient absorption and emission spectroscopy (Benabou *et al.*, 2014). The property of these motifs to reversibly fold or unfold with the change in pH has been exploited in designing nano-machines (Liu and Balasubramanian, 2003; Son *et al.*, 2014; Wang *et al.*, 2010).

Predicting Nucleic Acids Secondary Structures

With the wealth of sequence information available due to the advancements in sequencing technologies, there is a steep increase in secondary structure prediction algorithms (Schroeder, 2009; Shapiro *et al.*, 2007). Realizing the importance of RNA secondary

Fig. 5 Structure of G-quadruplexes. G-quadruplexes form in vitro in DNA or RNA sequences containing tracts of three to four guanine. (A) The building blocks of G-quadruplexes are G-quartets that arise from the association of four guanines into a cyclic arrangement stabilized by Hoogsteen hydrogen bonding (N1–N6 and N2–N7). The planar G-quartets stack on top of one another, forming four-stranded helical structures. G-quadruplex formation is driven by monovalent cations such as Na^+ and K^+ . (B) G-quadruplex structures are polymorphic and can be sub-grouped into different families, as for example parallel or antiparallel according to the orientation of the strands and can be inter- or intramolecular folded. Figure taken from Rhodes, D., Lipps, H.J., 2015. G-quadruplexes and their regulatory roles in biology. *Nucleic Acids Research* 43, 8627–8637.

structures, various algorithms and methods have been developed over the years (Schroeder, 2009). Accurate and reliable prediction of RNA secondary structure is a long but persisting challenge and predicting pseudoknots is even more challenging and hence some algorithms do not predict pseudoknots in the input RNA sequence. The various algorithms can be divided into two categories of software: (1) those that do not identify pseudoknots and (2) identify pseudoknots.

Programs for Predicting Secondary Structures Without the Pseudoknots

The *Unified Nucleic Acid Folding* or *UNAFold* (Markham and Zuker, 2008) constitutes a set of algorithms that simulate folding, hybridization and melting pathways for input nucleic acid sequence. *UNAFold* uses the Zuker algorithm (Zuker and Stiegler, 1981) for finding the minimum free-energy structure for a given sequence. Another software package *RNAstructure* can predict as well as analyze secondary structures in input DNA or RNA sequences (Bellaousov *et al.*, 2013; Reuter and Mathews, 2010) with various

base-pairing probabilities. The accuracy of prediction can be improved by incorporating experimental mapping data. The *Vienna RNA Websuite* (Gruber *et al.*, 2008) is a web-platform that provides users an access to various programs for designing and analysis of RNA sequences. It can predict folding of single and aligned sequences as well as RNA-RNA interactions. Using this websuite, it is also possible to design a sequence with a given structure.

Programs for Predicting Secondary Structures With the Pseudoknots

RNA-STAR predicts the secondary structure of linear RNA by simulating a hypothetical process of folding (Abrahams *et al.*, 1990) and uses the concept of local trigger regions for folding. RNA-STAR allows the RNA to fold into pseudoknotted structures during the simulation. Another program PKNOTS (Rivas and Eddy, 1999) generates the optimal minimum energy structure for an input RNA sequence. It uses standard RNA folding thermodynamic parameters along with parameters describing the thermodynamic stability of pseudoknots. However, due to the complexity of the algorithm, it can be computationally expensive for sequences with length > 100 nucleotides. NUPACK (Dirks and Pierce, 2003) is a dynamic programming algorithm that computes the partition function and hence finds the minimum energy structure. It also provides probabilities for various base pairs (bps) in a pseudoknot. The ILM (Ruan *et al.*, 2004) program is an iterative loop matching algorithm that allows the addition or subtraction of bps in different iterations to form pseudoknots and maximize bps. This method can be applied for individual and aligned sequences as it may use both thermodynamic or comparative information. HotKnots (Ren *et al.*, 2005) is a heuristic algorithm that predicts RNA secondary structures including pseudoknots. It tends to find a stable stem by an iterative process and uses a free energy minimization algorithm for pseudoknot free secondary structures that allows identification of potential candidate stems. A comparatively new and updated semi-automated algorithm, ConStruct (Wilm *et al.*, 2008) aligns multiple RNA sequences to find a consensus RNA structure and hence combines both thermodynamic stability and phylogeny information. The interactive graphical interface makes this program more user-friendly. Using a combination of various algorithms, it can predict tertiary interactions as well. A very recent algorithm TurboFold2 (Tan *et al.*, 2017) is an updated version of TurboFold (Harmanci *et al.*, 2011) and predicts secondary structures for multiple RNA homologs. TurboFold 2 has advantage over the TurboFold as it also provides a multiple sequence alignment, incorporating information from the conservation of secondary structures. ProbKnot (Bellaousov and Mathews, 2010) and TurboKnot (Seetin and Mathews, 2012) are other programs for predicting pseudoknots in input RNA sequences.

Prediction of 3D Structure

Prediction of tertiary structure of DNA/RNA is much more difficult with a wide gap between the sequence and structural space. Double helices have three rotational (tilt, roll and twist) and three translational (shift, slide and rise) base paired dinucleotide step parameters. These six parameters along with intra bp parameters (buckle, propeller, opening, shear, stretch and stagger) and local helical parameters (inclination, tip, displacement and rise) can be exploited to build a nucleic acid model. Programs like NUCGEN (Bansal *et al.*, 1995), 3DNA (Lu and Olson, 2008), Curves + (Blanchet *et al.*, 2011) and RNAHelix (Bhattacharyya *et al.*, 2017) use these parameters to build helical models with different sequences, but uniform or varying local step parameters. The 3D structures can be analyzed using various freely available algorithms like NUPARM (Bansal *et al.*, 1995), 3DNA (Lu and Olson, 2008), Curves + (Blanchet *et al.*, 2011) and DSSR (Lu *et al.*, 2015).

An early attempt at predicting RNA tertiary structure by Levitt in the 1969 has seen considerable progress with various algorithms being now available. ROSETTA (Das and Baker, 2008), MC-Sym (Parisien and Major, 2008), GARN2 (Boudard *et al.*, 2017) and F-RAG (Jain and Schlick, 2017) are few examples. ROSETTA uses the assembly of short fragments, taken from existing RNA crystal structures whose corresponding sequences match with a part of the target RNA. The generated models can be further refined to look more realistic. MC-Sym along with MC-Fold increases the accuracy of prediction of RNA 3D structure by using nucleotide cyclic motifs. GARN2 samples 3D RNA structure at a coarse-grained model and takes the corresponding secondary structure as input. Among all possible structures, it extracts two best possible structures that are close to the native one. F-RAG is a graph-based fragment assembly method that generates atomic coordinates from coarse-grained RNA models.

The second component of central dogma includes a process of decoding protein sequence from RNA and the process is called translation. Apart from DNA and RNA, proteins are the other major macromolecules that are important for the sustenance of life.

Proteins—Building Blocks of Life

The term 'Proteins' was first coined by Gerardus Johannes Mulder in his article titled 'On the composition of some animal substances' (Mulder, 1839), where he proposed that animals rely on plants for most of their protein. Since then, proteins have been the subject of extensive studies. Proteins are polypeptides comprising of 20 standard L-amino acids and their derivatives. These amino acids are covalently bonded through peptide bonds formed between the carboxyl and amide group of adjacent amino acid residues. Proteins are essential for survival and normal functioning of living cells and viruses. Almost all biological processes in a cell or group of cells involve proteins.

Proteins can be classified into different categories using numerous criteria such as biological roles, chemical composition and structure. Based on their biological roles, proteins are categorized into contractile, defense, enzymes, nutrients/storage, regulatory, structural, transport and other functional proteins. Using their compositions, proteins can be classified into two categories namely (1) simple and (2) complex. Simple proteins consist only of amino acids. Whereas, complex proteins contain prosthetic groups along with the amino acids in their structure. Based on their shape, proteins can be divided into two sets: fibrous and globular. Fibrous proteins are insoluble in water and have primarily mechanical and structural functions that provide support to the cells as well as the whole organism. The presence of hydrophobic amino acids on their surface facilitates their packaging into very complex supramolecular structures. Fibroin, collagen, α -keratins and elastin are few examples of this class. On the other hand, globular proteins are generally soluble in water or aqueous media containing acids, bases, salts or alcohol and more complex than the fibrous proteins. They have a compact and spherical/ovoid shape. The concept of tertiary and quaternary structures is usually associated with globular proteins only. The complex confirmation of globular proteins gives rise to a large variety of biological functions and makes them more dynamic rather than static in their activities. Defining the functional roles of a protein is essential considering the widespread influence every protein has towards the survival of an organism.

The first step towards deciphering the function of a protein involves understanding the physico-chemical properties of constituent amino acid residues containing an amide group, carboxylic group and a side chain 'R' (except glycine where hydrogen is present instead of R). There are 20 standard amino acids, which serve as building blocks of proteins. Amino acids can be categorized into 5 subgroups using the polarity and charge of side-chains (Nelson *et al.*, 2008): (1) Nonpolar (aliphatic R group: Ala, Gly, Ile, Leu, Met, Pro and Val), (2) Polar (uncharged R group: Asn, Cys, Gln, Ser, Thr and Tyr), (3) Aromatic (Phe, Trp and Tyr), (4) basic (positively charged R group: Arg, His and Lys) and (5) acidic (negatively charged R group: Asp and Glu). A covalent link ($-C(O)-NH$) between the carboxylic acid group of one and the α -amino group of the other amino acid is known as a peptide bond. It has a partial double bond nature thereby restricting rotation about the bond and conferring planarity (Pauling, 1960). However, considerable freedom for rotation prevails around the $N-C^\alpha$ and $C^\alpha-C$ bonds, giving rise to phi (ϕ) and psi (ψ) torsion angles (dihedral angles) respectively. In principle, (ϕ) and (ψ) can have any value between -180° and $+180^\circ$. However, certain values of (ϕ) and (ψ) are prohibited because they could result in steric clashes between atoms present in the polypeptide backbone as well as amino acid side chains. The polypeptide chain can take up the fully extended conformation with (ϕ, ψ) being $(-180^\circ, +180^\circ)$ resulting into the least steric hindrance. The peptide unit is most commonly characterized by *trans* conformation about the peptide bond in which the amide and carbonyl groups point in opposite directions. On the other hand, in *cis*-conformation, a less favorable conformation, both the amide and carbonyl groups in a peptide plane point in the same direction.

Using simple mechanized calculators, in 1963, G.N. Ramachandran and his coworkers predicted the possible allowed and disallowed combinations of the backbone dihedral angles (ϕ, ψ) by assessing the conformations of the two-linked peptide units for the presence of short contacts between non-bonded atoms in a polypeptide chain (Ramachandran *et al.*, 1963; Ramachandran and Sasisekharan, 1968; Ramakrishnan and Ramachandran, 1965; Sasisekharan, 1962). The map is popularly referred as Ramachandran map (Fig. 6). The predictions were found to be corroborating with the experimentally determined protein structure of myoglobin in 1958 (Kendrew *et al.*, 1958). The Ramachandran plot has repeatedly been reconsidered and redrawn during its first half century of life (Bansal and Srinivasan, 2013; Carugo and Djinovic-Carugo, 2013). However, several differences have been observed among various studies depending on: (1) the amount of data used, (2) data quality and (3) the criteria implemented. In fact, it is important to note that the original map used only theoretical computations when none of

Fig. 6 Ramachandran map representing the sterically favorable regions in white. Various regular secondary structural elements are shown at location corresponding to their Φ and Ψ values. Figure is reproduced from text book Mathews, van Holde, and Ahren, Biochemistry, third edition, 2000.

the protein structures were available in public domain, whereas nowadays, authors make use of experimental observations also. Ramachandran map is used extensively to assess the stereochemical quality of 3D structures of proteins as a part of validation tools like PROCHECK (Laskowski *et al.*, 1993), Moleman2 (Kleywegt and Jones, 1996), and more recently MolProbity (Davis *et al.*, 2004; Williams *et al.*, 2017).

Hierarchical Organization and Classification of Proteins

Proteins are organized in a hierarchical manner and can be illustrated by four major levels defined as primary, secondary, tertiary and quaternary structures (Fig. 7). Such tiered organization of proteins facilitates better understanding and comprehension of their 3D structures. Primary structure can be defined as a linear sequence of constituent amino acids in a polypeptide chain without specifying their spatial arrangements. Secondary structures correspond to recurring arrangements of adjacent amino acids in a polypeptide chain. There are mainly three types of secondary structure elements (SSEs) namely (1) helix, (2) strand and (3) turns (connects two SSEs). Apart from these three regular SSEs, there also exist irregular secondary structures also known as 'random coils'. Higher than the level of secondary structure there exists 'super-secondary structure', a specific combination of secondary structures with explicit spatial arrangements such as α and β hairpins or β - α - β motif (Rao and Rossmann, 1973). SSEs organize themselves in 3D space to form the corresponding tertiary structure that is driven mainly by the non-specific hydrophobic interactions. The quaternary structure specifies the spatial relationships amongst the various polypeptides in a functional protein complex. The extensive growth of protein sequence and structure information has resulted in the creation of numerous classification resources for organizing proteins (Redfern *et al.*, 2005).

Fig. 7 The hierarchical organization in protein structure. Human triose phosphate isomerase (Uniprot code: P60174, Protein Data Bank (PDB) code: 1HTI) has been taken as an example. The amino acid sequence of a protein is considered as its primary structure. Stretches of amino acids adopt regular secondary structures (such as α -helix, β -sheets – antiparallel and parallel, turns), which are connected by irregular secondary structures, termed as loops. The local secondary structures fold to provide the native and usually functional tertiary structure of a protein. For many proteins, the tertiary structure represents the biologically functional form. For several proteins, assembly of tertiary structures gives rise to the quaternary structure, which is the biologically functional form of that protein.

Based on Structure

Two main structure-based classification databases, Structural Classification of Proteins (SCOP) (Andreeva *et al.*, 2014; Lo Conte *et al.*, 2000; Murzin *et al.*, 1995) and Class Architecture Topology and Homology (CATH) (Orengo *et al.*, 1997, 2003; Pearl *et al.*, 2003) combine sequence, structure and functional information to provide a hierarchical classification of known protein domains in the PDB. Fold classification based on Structure-Structure alignment of Proteins (FSSP) (Holm and Sander, 1996) classifies protein structures based on the pair-wise structural comparison using DALI program (Holm and Sander, 1996).

The focus of SCOP is to structurally characterize the proteins that are deposited in the PDB. SCOP considers evolutionary and structural domains of proteins and classifies them in a hierarchical manner. However, in the recently released version of SCOP, SCOP2 (Andreeva *et al.*, 2014), these relationships form a complex network of nodes representing a relationship of a particular type and is illustrated by a region of protein structure and sequence. Here we are describing the hierarchy of classification in SCOP database (Fig. 8).

- i. Class (secondary structure composition and sequence/arrangement): members of different folds are placed under same class based on the extent of secondary structural content and order of occurrence of SSEs. Domains in globular proteins are usually classified under the following categories of 'Class'.
 - a. All α class: members in this class are predominately composed of helices.
 - b. All β class: members in this class are predominantly composed of β -sheets.
 - c. α/β class: members comprise of interspersed helices and β strands in their structure.
 - d. $\alpha + \beta$ class: members comprise of segregated helices and β strands in their structure.
 - e. Multidomain class: a multidomain class comprises of members with domains of different folds.
 - f. Small proteins: this class includes members corresponding to several disulfide rich and metal binding proteins with few or almost no regular secondary structures.
 - g. Membrane proteins: this class includes membrane proteins.
- ii. Fold (gross structural similarity): members in different superfamilies are grouped into one fold if the arrangement of major SSEs along with their topological connections is the same. Structural similarity among members in the same fold group arises from physicochemical properties favoring certain packing arrangements and chain topologies.
- iii. Superfamily (probable evolutionary relationship): families showing overall structural similarity and in many cases gross functional similarity, thus indicating potential common evolutionary origin, are categorized into one Superfamily. Sometimes although the functions are not the same for the families within the superfamily, the nature of functions along with the topological and chemical equivalence of functional sites imply the potential evolutionary relationship between the families.
- iv. Family (clear evolutionary relationship): family can be defined as a collection of related protein regions, which share high sequence identity and usually good functional and structural similarity. Most of the members of a family show more than 30% sequence identity with each other. However, there exist few examples of families in SCOP containing members with low sequence similarity to the globin family where sequence identity between members could be as low as 15%. However, all

Fig. 8 Levels of classification in the database of Structural Classification of Proteins (SCOP).

members show the same overall structure and critical functional residues in topologically equivalent positions thus implying divergence from a common ancestor.

Based on Sequence Similarity

Protein sequences have been classified into different domain families based on sequence identity among sequences. Different databases which considers sequence identity as a major feature to classify proteins are Protein Family (Pfam) (Punta *et al.*, 2012), Simple Modular Architecture Research Tool (SMART) (Letunic *et al.*, 2015), InterPro (Mitchell *et al.*, 2015) and Protein Domain (ProDom) (Bru *et al.*, 2005). Homology searches in databases of sequence similarity based protein domain families are efficient and their coverage is higher than searches in structural databases as the number of sequences is higher than the number of structures.

Various Secondary Structural Elements in Proteins

The concept of repeating backbone torsion angles ((ϕ, ψ)) or any other geometrical parameters along with the pattern of main chain-main chain (MM) N-H...O H-bonds defining a regular SSE in proteins is well established. The α -helices and extended β -strands, which are major regular SSEs found in proteins, were first predicted from theoretical studies (Pauling and Corey, 1951; Pauling *et al.*, 1951) and subsequently confirmed by X-ray diffraction analysis (Blake *et al.*, 1965; Perutz, 1951). Other SSEs like 3_{10} -helix (Donohue, 1953), π -helix (Low and Grenville-Wells, 1953), PolyProlineII (PPII)-helix (Cowan and McGavin, 1955) and left-handed α , 3_{10} and π -helices were also proposed from model building studies and found to occur occasionally (Ramachandran and Sasisekharan, 1968). Table 2 enlists various parameters of these SSEs. They have found their importance in a number of structural biology applications, such as structure comparison (Gibrat *et al.*, 1996), visualization (Humphrey *et al.*, 1996; Sayle and Milner-White, 1995; Schrodinger, 2010) and classification (Murzin *et al.*, 1995; Orengo *et al.*, 1997). The formation of SSEs plays a major role in protein folding also (Murzin *et al.*, 1995; Orengo *et al.*, 1997).

α -Helices

Of all the postulated helices in proteins, α -helices are the most abundant and the first to be identified (Kendrew *et al.*, 1958; Pauling *et al.*, 1951). These helices have 3.6 residues per turn and 13 atoms in the ring formed by $\text{NH}_{(i+4)} \rightarrow \text{O}_i$ H-bonds (represented as 3.6_{13}) (Kendrew *et al.*, 1958; Pauling *et al.*, 1951). The model successfully explained the overall distribution of intensities in the fiber diffraction patterns for the fibrous proteins, recorded earlier by Astbury in early 1930s and for certain synthetic polypeptides. The helix was established as a familiar motif after the 3D structure of myoglobin using X-ray crystallography was solved (Kendrew *et al.*, 1958, 1960). The backbone dihedral angles ((ϕ, ψ)) of residues in ideal right-handed α -helices are $(-57^\circ, -47^\circ)$ that may vary for the constituent residues of the native α -helices. However, it appears that the sum of both dihedral angles ($(\phi)_i + \psi_{(i+1)}$) is approximately -105° . The amino acid side-chains protrude away from the helix axis and point roughly towards the N-terminus. This property has been used in preliminary, low resolution electron-density maps to determine the direction of the protein backbone (Terwilliger, 2010). The aggregate effect of the individual carbonyl groups (microdipoles) of the constituent residues, pointing along the helix axis, generates an overall dipole moment (Hol *et al.*, 1978). α -helix has attracted many world-renowned artists who have referred it explicitly in their work. The list of names includes Julie Newdoll in painting, Irving Geis in cartoon as well as Julian Voss-Andreae, Bathsheba Grossman, Byron Rubin and Mike Tyka in sculpture (Fig. 9(A–B)). Based on handedness of α -helix, it can be categorized into right-handed (clockwise) or left-handed (anticlockwise). Right-handed α -helices in protein structures outnumber their left-handed counterpart.

β -Strands

Besides α -helices, β -strands/sheets are another major SSE in globular proteins, which contain 20%–28% of all residues (Kabsch and Sander, 1983a,b). β -strands are the basic unit of a β -sheet, which can be considered as a helix with 2 residues/turn and

Table 2 Regular SSEs formed by polypeptide chains and their respective parameters. Plus and minus sign in 2nd column correspond to the right and left handed helices, respectively

Secondary structures	Residues per turn and chirality	Rise per residue ($\text{\AA}$)	Radius of helix ($\text{\AA}$)
α -helix	± 3.6	1.5	2.3
π -helix	$+ 4.3$	1.1	2.8
3_{10} -helix	$+ 3.0$	2.0	1.9
Planar parallel sheet	± 2.0	3.2	1.1
Planar anti-parallel sheet	± 2.0	3.4	0.9
Twisted parallel or anti-parallel sheet	$- 2.3$	3.3	1.0

sheet. Two interacting strands of a sheet can be arranged either in (1) anti-parallel or (2) parallel to each other (**Fig. 9(C)** and **(D)**). Antiparallel strands are commonly found in sheets. However, about 20% of the β -sheets are observed to have both parallel and antiparallel strands (**Richardson, 1977**). Although parallel β -strands usually form large, moderately twisted sheets, occasionally it forms a cylinder with helices being present at outside as in triosephosphate isomerase structure. On the other hand, large antiparallel sheets, usually roll up either partially (first domain of thermolysin or in ribonuclease) or entirely to join edges facilitating the formation of a cylinder or barrel (membrane-spanning proteins such as porins). The connection between the two strands of a sheet can be divided into two categories namely (1) hairpin connection and (2) crossover connection (**Richardson, 1981; Sternberg and Thornton, 1976, 1977a,b**). In hairpin connection, the backbone enters and exits from the same end of the sheet, while the backbone enters and exits from the opposite end in crossover connection. Though right-handed crossovers are the rule in globular proteins, quite a few examples of left-handed crossovers are also observed (e.g., subtilisin and glucose phosphate isomerase).

3₁₀-Helices

Besides the classical α -helices and β -sheets, the only other principal helical species, which occurs to any great extent in globular protein structure, is the 3₁₀-helix with a three-residue repeat and a H-bond between NH group of residues 'i + 3' instead of 'i + 4' and CO group of ith residue (**Fig. 9(B)**). This structure was first proposed by **Taylor (1941)** and later discussed in detail by **Huggins (1943)**, **Bragg et al. (1950)** and **Donohue (1953)**. Its backbone conformational angles are approximately $(\varphi) = -49^\circ$, $(\psi) = -26^\circ$ (**Ramachandran et al., 1966**), which lie within the same energy minimum as of the α -helix. However, for a long periodic structure, the 3₁₀-helix is considerably less favorable than the α -helix in terms of both local conformational energy and geometry of H-bonds. The same is evident by the less frequent occurrence of longer 3₁₀-helices (**Kumar and Bansal, 2015a,b**). Though long 3₁₀-helices are very rare, shorter 3₁₀-helices occur quite frequently (**Toniolo and Benedetti, 1991**). A survey of 57 crystal structures, showed that 3.4% of total residues are involved in 3₁₀-helix (**Barlow and Thornton, 1988**). A total of 132, 3₁₀-helices with six amino acids or more were observed by **Pal and Basu (1999)**. Another structural analysis of 1774 3₁₀-helices spanning five residues or more from highly resolved (resolution better than 1.6 Å) 689 protein chains with sequence identity being $\leq 20\%$ revealed that they occur quite frequently, but the longer helices are irregular (**Enkhbayar et al., 2006**). They are often found at the termini of α -helices. Structures of three potassium channels of the six transmembrane (TM) helix type and solved by x-ray crystallography (**Clayton et al., 2008; Long et al., 2005a,b**) revealed that the fourth TM segment of each subunit adopts a 3₁₀-helical conformation spanning 7–11 residues.

π -Helices

The discovery of α -helices triggered a race for finding various other possible helices. Donohue predicted the occurrence of 2.2₇, 3₁₀, 4.3₁₄ and 4.4₁₆ helices (**Donohue, 1953**), whereas Low and Baybutt independently suggested the possibility of the 4.4₁₆ or π -helix (**Low and Baybutt, 1952**). The π -helices are often characterized by the presence of a repeating pattern of H-bond between the backbone C=O of residue 'i' and the backbone HN of residue 'i + 5' (**Fig. 9(B)**). π -helices have, therefore, been described as α -aneurisms (**Keefe et al., 1993**), α -bulges (**Cartailler and Luecke, 2004**) or π -bulges (**Hardy et al., 2000**). The sum of dihedral angles $((\varphi)_i + \psi_{(i+1)})$ is approximately -125° , whereas the angle τ (N-CA-C') is larger (114.9°) than the standard tetrahedral angle of 109.5° . The side chains in π -helices are more staggered than the ideal 3₁₀-helix, but not as well in the α -helix. Like 3₁₀-helices, a majority of π -helices are found in conjunction with the α -helices. The large majority of naturally occurring π -helices consist of five residue segments with the minimal two π -type (NH_(i+5) → O_i) H-bonds (**Fodje and Al-Karadaghi, 2002**). The functional roles of π -helices have featured in various reports and the correlated presence of such helices with the active sites in proteins (**Medlock et al., 2007; Weaver, 2000**).

PolyProlineII-helices

The PPII-helix is an extended, flexible left-handed helix without intra-helical H-bonds (**Fig. 9(E)**). The backbone dihedral angles of constituent residues are restricted to around $((\varphi) = -75^\circ$, $(\psi) = 150^\circ$). They play an important role in structural proteins, unfolded states and as ligands for signaling proteins. The analysis of main chain conformations in proteins have shown that the left-handed PPII-helices are quite common in globular proteins (**Adzhubei and Sternberg, 1993; Kumar and Bansal, 2016**). Another survey of 274 non-homologous protein structures revealed that longer PPII-helices are rare, but at least one PPII-helix is present in the majority of proteins (**Stapley and Creamer, 1999**). Most PPII-helices are shorter than five residues. Though PPII-helices have a high preference for Pro residues, there is evidence for the presence of PPII conformations in helices containing non-Pro residues (**Makarov et al., 1975; Tiffany and Krimm, 1968; Woody, 1992**). A majority of the PPII-helices are solvent exposed and found to be frequently involved in protein-protein interactions (**Berisio and Vitagliano, 2012**). PPII-helix is observed to have a direct involvement in host-pathogen recognition for virus infections (**Vermeire et al., 2011**). These helices are also found to activate the phosphatidylinositol 3-kinase (PI3K)/Akt signaling pathway by the influenza-A virus (**Hale et al., 2010**). Recent advancements in identifying PPII-helices are well explained by **Narwani et al. (2017)**.

Collagen Triple Helix

Collagen is a fibrous protein which is present in abundance in the human body, being a major constituent of skin, bones as well as various connective tissues. It helps in forming a scaffold to provide strength and structure. Collagens have a unique tripeptide repeat sequence with Glycine at every third position and the iminoacids Proline and Hydroxyproline often being present at the other two positions (Bowes and Kenten, 1948; Eastoe, 1955). The first triple helical structure of collagen had two inter chain H-bonds for every three residues (Ramachandran and Kartha, 1954, 1955). This was slightly modified to a one hydrogen-bonded structure (Rich and Crick, 1955). However a second water mediated hydrogen bond is also found to stabilize the triple helix (Ramachandran and Sasisekharan, 1961). Each helix in collagen has left handed screw sense and the major helix formed by three such helices is right handed. Each helix has 10 residues in 3 turns resulting in a pitch of 85.8 Å. The twist between two neighboring helices was found to be -108.8° and rise of ~ 2.86 Å (Bhattacharjee and Bansal, 2005; Ramachandran and Kartha, 1955; Ramachandran and Sasisekharan, 1961). Molecular defects in biosynthesis of collagen can lead to many rare genetic diseases involving connective tissues like Ehlers-Danlos syndrome (De Paepe, 1998; Gaisl *et al.*, 2017; Miyake *et al.*, 2017; Prockop *et al.*, 1979). Collagen has been shown to have wide range of applications in the medical and cosmetic field as it is biodegradable, biocompatible, easily available and weak antigenic (Cheng *et al.*, 2017; Chvapil, 1977; Chvapil *et al.*, 1973; Lee *et al.*, 2001; Sheikh *et al.*, 2017). In the field of tissue engineering, collagen based biomaterials are used to improve tissue functions (Parenteau-Bareil *et al.*, 2010).

Turns

A turn is a region of the protein, which consists of four consecutive amino acids and allows the polypeptide chain in folding back on itself by nearly 180° (Fig. 9(F-G)). Venkatachalam (1968) explored all the plausible available conformations to a system of three linked peptide units consisting of four successive residues that can be stabilized by a backbone H-bond between the CO of residue 'i' and the NH of residue 'i + 3'. The resultant non-repetitive SSE, recognized from the theoretical conformational analysis, were termed as 'Turns'. He proposed three unique conformations based on $((\phi, \psi))$ values (Turn I, II and III) along with their mirror images having $((\phi, \psi))$ signs reversed (I', II' and III'). Lewis *et al.* (1973) analyzed the turns in a large dataset of 3D protein structures and proposed a more general definition using the distance (d) between the $C^\alpha(i)$ and the $C^\alpha(i + 3)$. The distance 'd' should be < 7 Å to be a part of turn. Kuntz (1972) and Chou and Fasman (1977) have found 45% and 32% of protein chain in turns respectively. At the same time, considering only the central dipeptide, Zimmerman and Scheraga found 24% of the non-helical residues in turns (Zimmerman and Scheraga, 1977). Turns are also known as reverse turns, β -turns, β -bends, hairpin bends, 3_{10} -bends, kinks or widgets, among others. Helices and strands are often connected to each other by the tight turns. It has also been suggested that turns can direct the process of protein folding to the native conformation as they are best suited to provide the decisive long-range interactions that form tertiary structure (Lewis *et al.*, 1971; Rose *et al.*, 1976). Few proteins have been reported to have structure, which is heavily dependent on turns. For example, high-potential iron protein consists of 17 turns in 85 residues (Carter *et al.*, 1974). Type-I and Type-II along with their mirror images I' and II' are most abundant types of turns.

Other SSEs

This class includes rarely occurring helices like 2.2_7 -helices or left handed α , 3_{10} or π -helices. The repetitive C7 structure, the 2.2_7 helix or 2.2_7 ribbon, was first proposed for polypeptides by Donohue (1953) and later it was considered theoretically with $((\phi) = -78.1^\circ, \psi = 59.2^\circ)$ (Ramachandran and Sasisekharan, 1968) for further studies. The 2.2_7 -helix is a tight helix of 2.2 amino acids per turn and a 7 atom loop, closed by the H-bond between $NH_{(i+2)}$ and O_i . So far, this structure has not been reported in protein crystal structure.

The analysis of 31 verified left-handed helices from a set of 7284 proteins suggests that despite being rarely found in proteins, when they occur, they have structural or functional significance (Novotny and Kleywegt, 2005). Backbone dihedral angles (ϕ) and ψ of residues in left-handed helices are found to range from 30° to 130° and -50° to 100° respectively, a mirror image of the residues in right-handed helices.

Computational Approaches for Identification of Secondary Structures in Proteins

SSEs define a protein motif and under physiological conditions almost all protein sequences have at least one 3D structure that determines their biological function. In this section, the computational methods developed for prediction/assignment of different SSEs from input sequence/protein structures are discussed.

Prediction of Secondary Structures Using Protein Sequences

One can find the root of protein secondary structure prediction in 1951, when the models for helix and sheet were proposed by Pauling and Corey (1951) and Pauling *et al.* (1951). Prediction of SSEs in bioinformatics aims to predict the local secondary structures of proteins based only on knowledge of their amino acid sequence. The prediction consists of classifying regions of the

amino acid sequence into helices, β -strands or turns. Interest in developing the methods for predicting the secondary structures in protein started as soon as the first crystal structure was solved. These methods (Guzzo, 1965; Kotelchuck and Scheraga, 1969; Lewis *et al.*, 1970; Prothero, 1966; Schiffer and Edmundson, 1967) focused mainly on identifying regions, which are most likely to take α -helix conformation. With the increase in the number of solved protein structures, significantly improved algorithms were developed in 1970s. However, these methods attained the accuracy of 60%–65% and often under-predicted the strands (Mount, 2004). More than 20 different SSEs prediction methods have been reported till date. Some of them are shown in Fig. 10(A).

The first major breakthrough came with the development of Chou-Fasman method (Chou and Fasman, 1974), which relies predominantly on the probability parameters determined from relative frequencies of appearance of different amino acids in each

Fig. 10 (A) Timeline of protein secondary structure prediction algorithms. Boxes colored in blue indicate that the algorithms are available as web-server only, while those in green are available as standalone. GOR method, colored in red is available as a web-server as well as standalone program; (B) Timeline of protein secondary structure assignment algorithms. Boxes colored in blue suggest that the algorithm uses 3D geometry, while programs in green colored boxes use (ϕ, ψ) and/or H-bond patterns for SSE assignment. Algorithms in red colored box are hybrid methods.

type of major SSEs. This method is almost 50%–60% accurate in predicting SSEs (Kabsch and Sander, 1983a,b) that is significantly less than the modern machine learning-based techniques (Mount, 2004).

The GOR method (Garnier *et al.*, 1978), named after three scientists Garnier, Osguthorpe and Robson, is an information theory-based method and Bayesian in nature. The GOR method considers the probability of each amino acid having a secondary structure as well as the conditional probability of the amino acid in each structure given that its immediate neighbors have already formed that structure. The original GOR method predicted the secondary structures with roughly 65% accuracy. The original method is more successful in predicting α -helices than β -strands (Mount, 2004).

Methods like PSIPRED (Jones, 1999), SPINE (Dor and Zhou, 2007) and JPRED (Drozdetskiy *et al.*, 2015) are based on neural networks and predict the secondary structures with over 70% accuracy. SPINE-X (Faraggi *et al.*, 2009) algorithm can accurately predict the dihedral angles of the residues and hence improved the *ab-initio* structure prediction of proteins.

Apart from using only amino acid sequence, considering various other factors like effect of local environment (Zhong and Johnson, 1992), solvent accessibility of residues (Macdonald and Johnson, 2001) and protein structural class (Costantini *et al.*, 2006) can improve the SSE prediction as they also affect the SSEs in proteins (Adamczak *et al.*, 2005; Costantini *et al.*, 2007; Momen-Roknabadi *et al.*, 2008). Though the recent improvement produces a better prediction of SSEs and in particular β -strands, still the constraints to the prediction has not reached and continue to rise (Rost, 2001; Yang *et al.*, 2016).

Assigning SSEs to 3D Structures

Knowing the importance of secondary structures as well as the increase in the number of experimentally solved 3D structures, several methods have been proposed over the years to identify the SSEs from the given 3D structure of proteins. Secondary structures possess regularities in various geometric parameters like C^α distances, dihedral angles and specific patterns of H-bonds that can be utilized as criteria to define them. In general, most of the methods can correctly identify the location of the core of helices and strands in proteins. However, precise assignment of termini is still a problem as they are very often ill-defined and difficult to determine unambiguously. These methods can be broadly classified into three categories: (1) algorithms based on $((\varphi), \psi)$ and/ or H-bond patterns (2) algorithms based on 3D geometry and (3) hybrid methods, which use both (1) and (2). Programs like DSSP (Kabsch and Sander, 1983a,b; Touw *et al.*, 2015), STRIDE (Frishman and Argos, 1995) and PROSS (Srinivasan and Rose, 1999) fall into the first category, DEFINE (Richards and Kundrot, 1988), P-CURVE (Sklénar *et al.*, 1989), P-SEA (Labesse *et al.*, 1997), SST (Konagurthu *et al.*, 2012) and ASSP (Kumar and Bansal, 2015a,b) come under second category, whereas KAKSI (Martin *et al.*, 2005) and PALSSE (Majumdar *et al.*, 2005) fall under the third category. A few programs that specifically identify π (Fodje and Al-Karadaghi, 2002) and PPII (Cubellis *et al.*, 2005; King and Johnson, 1999; Mansiaux *et al.*, 2011; Srinivasan and Rose, 1999) -helices have also been developed.

The first ever automated method for SSE assignment was developed by Levitt and Greer (1977) who used distance and virtual torsion angle made by C^α atoms over a sliding window of four residues. Breakthrough in assigning SSEs came with the introduction of more comprehensive and widely used algorithm known as 'Dictionary of Secondary Structure of Proteins' (DSSP) (Kabsch and Sander, 1983a,b; Touw *et al.*, 2015) that is based on the detection of H-bond patterns defined by an electrostatic criterion. DSSP is considered as the gold standard for SSE assignment and used in number of software packages like Rasmol (Sayle and Milner-White, 1995) and GROMACS analysis tools (Berendsen *et al.*, 1995). DEFINE-S (Richards and Kundrot, 1988) uses only C^α coordinates, compares their distances with the distances in ideal SSEs and also provides information about the super-secondary structures. P-CURVE (Sklénar *et al.*, 1989) assigns SSEs based on the helicoidal parameters and global peptide axis for peptide units. Another widely used algorithm known as STRIDE (Frishman and Argos, 1995) uses $((\varphi), \psi)$ along with H-bond pattern. STRIDE has been implemented in a visualization tool VMD (Humphrey *et al.*, 1996) for assigning SSEs. P-SEA (Labesse *et al.*, 1997) uses a short C^α distance mask and two C^α dihedral angles to assigns SSEs, while PROSS (Srinivasan and Rose, 1999) is solely based on backbone dihedral angles. Another algorithm, Xtlstr (King and Johnson, 1999) calculates backbone dihedral angles as well as distances and assigns SSEs that would be consistent with interactions of amide-amide groups observed from circular dichroism of a protein in the ultraviolet range. SECSTR (Fodje and Al-Karadaghi, 2002) is more sensitive to the π -helices. Using SECSTR, for the first time, authors reported the biasness of DSSP and STRIDE towards the α -helices. However the latest version of DSSP (Touw *et al.*, 2015) has addressed this problem and tried resolving it (Kumar and Bansal, 2015a,b). The algorithm PALSSE (Majumdar *et al.*, 2005) mainly uses distance and torsion angle constraints to identify core elements and later extends them to longer segments. Authors claim to assign SSEs up to 80% of the protein structure. KAKSI (Martin *et al.*, 2005) uses C^α distances and backbone dihedral angles to show the concordance with the assignments found in the PDB (Berman *et al.*, 2000) files. Another algorithm SST (Konagurthu *et al.*, 2012) uses minimum message length inference for the assignment of SSEs in protein structures. A comparatively new method 'Assignment of Secondary Structure in Proteins' (ASSP) uses only the path traversed by the C^α atoms of the consecutive residues (Kumar and Bansal, 2015a,b) and is an extension of HELANAL-Plus (Bansal *et al.*, 2000; Kumar and Bansal, 2012), a program for analysis of geometry of helices in proteins. The algorithm is based on the premise that a protein structure can be divided into uniform stretches that can be defined in terms of helical parameters and depending on their values, the stretches can be further classified into different SSEs, viz. α , 3_{10} , π , extended β -strands, PPII and other left-handed helices. Another, recently reported algorithm (Cao *et al.*, 2015) identifies α -helices along with 3_{10} and π -helices by dividing it into a minimization problem and a restraint satisfaction problem. It follows rigorously the geometry of helices. Brief description about various algorithms is tabulated in Table 3 and Fig. 10(B).

Table 3 Brief description of different secondary structure assignment algorithms

Sl. No.	Algorithm	Description	Reference
Category (i)			
1	DSSP	Detects the H-bond patterns using bond energy criterion	Kabsch and Sander (1983a,b)
2	STRIDE	Uses $((\varphi), \psi)$ along with H-bond pattern	Frishman and Argos (1995)
3	PROSS*	Uses only on the backbone dihedral angles $((\varphi), \psi)$	Srinivasan and Rose (1999)
4	SECSTR	Uses DSSP like H-bond definition and was developed to identify and analyze π -helices	Fodje and Al-Karadaghi (2002)
5	DSSP-PPII*	Identifies the PPII-helices in the region not assigned as a major SSE by DSSP and gives the output in the DSSP format	Mansiaux <i>et al.</i> (2011)
Category (ii)			
6	Levitt <i>et al.</i>	Uses distance and virtual torsion angle made by the C α atoms over a sliding window of four residues	Levitt and Greer (1977)
7	DEFINE-S	Uses only C α coordinates and compares the distance between various C α 's with the distances in ideal SSEs	Richards and Kundrot (1988)
8	P-CURVE	To start with, it chooses the successive repeating unit and does the analysis of mathematical analysis of protein curvature	Sklenar <i>et al.</i> (1989)
9	P-SEA	Solely based on the C α atoms. Uses three distance, one angle and one dihedral angle	Labesse <i>et al.</i> (1997)
10	XTLSSTR*	Calculates two angles and three distances for assigning SSEs. The algorithm is driven by the concept of circular dichroism (CD) of a protein in the far ultraviolet range.	King and Johnson (1999)
11	STICK	Finds a set of best fit axes and later takes the average rise of the residues along each axis	Taylor (2001)
12	SST	Uses minimum message length inference for SSEs assignment	Konagurthu <i>et al.</i> (2012)
13	ASSP*	Use C α atoms to identify the continuous stretches and later divides them into different SSEs	Kumar and Bansal (2015a,b)
Category (iii)			
13	KAKSI	Uses C α distances and backbone dihedral angles to show the concordance with the assignments found in the Protein Data Bank	Martin <i>et al.</i> (2005)
14	PALSSE	Mainly uses distance and torsion angle constraints to identify core elements and later extends them to longer segments	Majumdar <i>et al.</i> (2005)
15	SEGNO*	The C α atoms along with the backbone dihedral angles $((\varphi), \psi)$ and the angle-distance H-bond	Cubellis <i>et al.</i> (2005)

Source: Sklenar, H., Etchebest, C., Lavery, R., 1989. Describing protein structure: A general algorithm yielding complete helicoidal parameters and a unique overall axis. *Proteins: Structure, Function, and Bioinformatics* 6, 46–60.

The algorithms are divided according to the categories mentioned in the main text. Algorithms marked by "*" identify PPII-helices also along with other SSEs.

A comparative analysis of number of residues identified as being part of α -helices by different algorithms suggests that there is on an average $\sim 80\%$ agreement (Kumar and Bansal, 2015a,b). However, it has also been observed that many algorithms prefer α -helices over π - or 3_{10} -helices (Fodje and Al-Karadaghi, 2002; Kumar and Bansal, 2015a,b; Shelar *et al.*, 2013). For example, residues Thr87-Leu134 of Oxidoreductase protein (PDB ID: 1SY: A) have different residue-wise assignments by various algorithms. Surprisingly the program XTLSSTR assigned extended β -strand to the residues Glu120-Ala121, whereas the same segment remained unassigned by ASSP and DSSP (Fig. 11). Differences in the assignments by various algorithms suggest that one cannot have a single algorithm that works well for every protein structure and hence one should be careful in selecting an algorithm.

Experimental Approaches for Identification of Secondary Structures

Circular dichroism (CD): CD uses the differential absorption of left- and right-handed light by chromophores with intrinsic chirality or placed in a chiral environment. Proteins, in general, contain various chromophores that engender CD signals. CD spectroscopy can provide the information about the SSEs content, any conformational changes upon ligand binding or macromolecular interactions. The thermal stability of the biomolecule can also be studied (Kelly and Price, 2000). The CD spectrum obtained in the far UV region (260–190 nm) corresponding to the peptide bond absorption can delineate the content of SSEs like α -helix and β -sheet; whereas the spectrum in near UV region (320–260 nm) provides an information about the environment around the aromatic amino acids or chromophores and hence about the tertiary structure. Units used in CD are ellipticity (measured in millidegrees and represented as θ) or mean residue ellipticity (MRE and represented as $[\theta]$). Several web-servers use MRE values from the CD-spectrum to provide the percentage SSE content of the protein (Louis-Jeune *et al.*, 2012; Micsonai *et al.*, 2015; Perez-Iratxeta and Andrade-Navarro, 2008; Sreerama and Woody, 2000; Whitmore and Wallace, 2004; Wiedemann *et al.*, 2013). Web-servers are also available to predict the CD

Fig. 11 Pictorial representation comparing the secondary structure assigned by different algorithms. Amino acid residues Thr87-Leu134 of Oxidoreductase protein (PDB ID: 1SYI; chain: A) is taken as an example.

spectrum of a modelled protein (Bulheller and Hirst, 2009; Mavridis and Janes, 2017). The updated version of CD is Synchrotron radiation circular dichroism (SRCD) spectroscopy that enhances the usage of conventional CD. The high light flux allows the collection of data at lower wavelengths, detection of spectra with higher signal-to-noise levels and measurements in the presence of strongly absorbing solvents also. Please refer to the reviews elsewhere (Kelly *et al.*, 2005; Kelly and Price, 2000; Miles and Wallace, 2006; Wallace, 2009) for better understanding and recent progresses in the field. CD and SRCD spectra as well as metadata can be deposited to open access data bank named PCDDDB (Whitmore *et al.*, 2017).

Knowledge of the 3D structures of biomolecules helps in understanding their function. At the same time, they can also provide an information about the SSEs that may be more accurate than CD. X-ray crystallography, NMR or cryo-electron microscopy are the most commonly used methods for solving 3D structures.

X-ray crystallography: this field uses the fundamentals of X-ray diffraction and mathematical approaches to symmetry to solve the structure of a biomolecule. Since 1957, the year in which the first crystal structure of myoglobin (Kendrew *et al.*, 1958) was solved, the field has helped researchers to understand the cellular processes in more detail and facilitated the advancement of modern medicines as well. The field has attracted more than 25 Nobel Prizes, starting in 1915 with the Bragg father-and-son team. Though the work on DNA double helix fetched noble prize to Watson and Crick in 1953, the structure of a 12-base-pair palindromic DNA was finally solved in 1980 by the X-ray crystallography method (Wing *et al.*, 1980). As of now, 30th September 2017, almost 90% of the total deposited structures in PDB are solved by this method. Few recent reviews elsewhere (Garman, 2014; Ilari and Savino, 2008; Powell, 2016; Shi, 2014; Smyth and Martin, 2000) can be an interesting read.

Nuclear Magnetic Resonance (NMR): two independent studies laid the foundation for a new technique, NMR (Bloch, 1946; Purcell *et al.*, 1946). For this pioneer work, Edward Mills Purcell and Felix Bloch received the 1952 Nobel Prize in Physics. NMR exploits the magnetic properties of certain atomic nuclei and can provide detailed information about the structure, dynamics, reaction state, and chemical environment of molecules. As of 30th September 2017, almost 12,000 three-dimension structures solved by NMR have been deposited in PDB. For better understanding of NMR spectroscopy, one can refer to available books (Abraham, 1978; Callaghan, 1993; Hore, 2015).

Cryo-electron microscopy (Cryo-EM): use of electrons in place of X-rays has a lot of advantages as they can be scattered more strongly and can be accelerated by electric fields. 3D structures of large biological assemblies in solution or cell can be well studied using 3D electron microscopy (3DEM) (Frank, 2011). Application of EM in biological specimens has seen a steep rise in popularity since the first electron microscope was developed and bacteriophages were imaged by the Ruska brothers (Ruska, 1941; Ruska *et al.*, 1939). Cryo-EM imaging technique requires much less sample compare to NMR or X-ray crystallography and have fewer restrictions on sample purity. There are mainly three categories of cryo-EM namely (1) Cryo-electron tomography, (2) single-particle cryo-EM and (3) electron crystallography. These sub-disciplines are either used in isolation or combined with other techniques to analyze biological structures in different contexts. The recent advancements in direct electron detectors have improved the resolution of the structures solved by cryo-EM such that in atomic resolution is now achievable (Grigorieff, 2013; Ruskin *et al.*, 2013). The gain in popularity of this method can be gauged by the fact that many reviews detailing the methodological advances are published every year (Milne *et al.*, 2013). Currently there are almost 1750 structures, solved by EM that have been deposited in PDB.

Distortions in Regular SSEs

The departure from the ideal values of the geometric parameters for a given SSE is often called distortions and most of the SSEs in protein structure possess it. Occurrence of $(i + 4 \rightarrow i)$ NH...O H-bonds between the amino acids in the main-chain, makes the α -helices quite uniform in terms of geometric parameters. However, most helices in proteins are curved (Barlow and Thornton, 1988; Kumar and Bansal, 1998) and deviate from the ideal values of defining parameters that can be because of the solvent induced distortions (Blundell *et al.*, 1983), peptide bond distortions (Barlow and Thornton, 1988; Love *et al.*, 1972) or presence of Pro (Chakrabarti *et al.*, 1986; MacArthur and Thornton, 1996). Blundell and coworkers (Blundell *et al.*, 1983) did the first survey on the curvature of helices to conclude that the majority of the helices are curved. Distortions caused by Pro residues (Chakrabarti *et al.*, 1986; Chakrabarti and Chakrabarti, 1998; MacArthur and Thornton, 1996; Sankaramakrishnan and Vishveshwara, 1990, 1992), Ser and Thr residues (Ballesteros *et al.*, 2000; Deupi *et al.*, 2004) residues have also been studied. An

interesting study of kinks caused by Pro residues in α -helices of transmembrane proteins (Yohannan *et al.*, 2004) reveals that the kinks are preserved even after the mutation of the Pro to other amino acids. These distortions in the helices do not allow the helix axis to follow a straight path. Recently, the analyses of simple insertions in α -helices of the coiled-coil structure has revealed that the insertion switches the coiled-coils into a novel fibrous protein fold (α/β coiled-coil) consisting of periodically interspersed short β -strands (Hartmann *et al.*, 2016). The interspersed π -helices are quite often considered as distortions in α -helices and often termed as α -aneurisms (Keefe *et al.*, 1993), α -bulges (Cartailler and Luecke, 2004) or π -bulges (Hardy *et al.*, 2000). The above mentioned belief was generally due to the biasness towards the α -helices (Fodje and Al-Karadaghi, 2002; Kumar and Bansal, 2015a,b). However, the presence of π or 3_{10} -helix distorts the entire helical segment by providing large bend (Kumar and Bansal, 2015a,b). Study has also shown that naturally occurring π -helices are evolutionarily related to α -helices (Cooley *et al.*, 2010).

Distortions in β -strands have also been reported (Blake and Oatley, 1977; Richardson *et al.*, 1978). One such distortion is a β -bulge that can be defined as a region between two consecutive β -type H-bonds that includes two residues on one strand and a single residue on the other strand (Richardson *et al.*, 1978). They occur very frequently in the coil regions, but are most easily visualized as local distortions in anti-parallel strands. Compared to parallel β -strands, it is generally believed that the anti-parallel strands are more stable as they can withstand greater twisting and other distortions like β -bulges and exposure to solvents. Only about 5% of the β -bulges were found between parallel strands (Richardson, 1981). Though β -bulges can be classified into several types, classic β -bulge occurs most frequently in the protein structures followed by 'G1', 'Wide' and 'parallel and GX' bulges. Classic β -bulge occurs between a narrow pair of H-bonds on anti-parallel strands and has the side chains of constituent residues in the same side of the β sheet, while G1 bulges can be defined as a classic bulge with Gly residue at the position 1. 'Wide type' β -bulges occur between a widely spaced pair of H-bonds on anti-parallel strands. GX bulges are the most unusual bulges and often contain Gly residue at position X. β -bulges affect the directionalities of the protein chain in the 3D structure, making them useful for determining the large features of β -sheet and/or extended hairpin loops.

A twist in the β -strands of a sheet can also be considered as a distortion as it introduces local conformational irregularities into the polypeptide backbone. Nevertheless, an extremely strong local twist helps to close the anti-parallel β -barrels containing five or six strands. Sheets with a right handed twist are more common and have a lower free energy than their straight or left-handed counterparts (Chothia, 1973).

Protein Structure and Sequence Repositories

PDB (Berman *et al.*, 2000) is the most comprehensive repository of structure data for biological macromolecules. The repository contains the primary structure and secondary structure information along with the atomic coordinates of a constituent atoms of biomolecule. It also contains corresponding experimental data. PDB101, an education portal of PDB provides detailed information about the PDB. As of 27th September 2017, PDB contains structure data for 133,920 Biological Macromolecular Structures (Fig. 12). On an average, the length of proteins ranges between 100 and 300 residues. However, there are big proteins containing 1000 or more residues as well as small proteins with at most 30 residues.

A dedicated data bank, EMDataBank (Lawson *et al.*, 2016), is also available online at EMDataBank (see Relevant Websites section) that is a unified global portal for deposition and retrieval of 3DEM density maps, atomic models, associated metadata and related stuffs. It has 5195 EMDB map entries, 1805 PDB coordinate entries as of 30th September 2017.

The 3D structures of experimentally-determined nucleic acids and complex assemblies can be deposited into a databank called nucleic acid database (NDB) (Coimbatore Narayanan *et al.*, 2014). The repository contains the sequences of the corresponding nucleic acid chain along with the derived geometric data, classifications of structures and motifs, standards for describing nucleic acid features. It is also linked to various software for the analyses. As of 27th September 2017, number of released structures in NDB is 9133.

Apart from PDB, NCBI (Geer *et al.*, 2010) and UniProt (Consortium, 2015) databases also provide comprehensive, high-quality and freely accessible resource of protein sequence and functional information. Another very important database, Pfam (Punta *et al.*, 2012), contains a large collection of protein families, each represented by multiple sequence alignments and Hidden Markov Models. The PDB ID of the members of each family is linked to the PDB database.

Several initiatives have been taken in the past to classify proteins into groups based on properties that are shared by all protein members of a group. Different properties such as structural similarity, sequence similarity and functional similarity have been employed to classify proteins. Classifying proteins in such a manner is especially useful in functional annotation of proteins which are newly discovered from genome sequence data. Also, it has been useful in predicting tentative structures for proteins with no 3D structural data.

Protein 3D Structure Prediction and Analyses

Protein structure prediction and engineering-design aim to fill the huge gap between the sequence and structure space. The protein structure prediction methods can be categorized into mainly three parts (1) *ab initio* methods (2) Threading (3) Homology modelling. The evolutionary information from the genomic sequences can be utilized efficiently to compute the protein 3D structures from their amino acid sequences (Marks *et al.*, 2012). The *ab initio* (*de-novo*) methods are based on the first

Fig. 12 Number of 3D structures deposited in the PDB on yearly basis as of 30th September 2017.

principle laws of physics as well as chemistry and based on the fact that the native structure of protein is always at energy minimum. Using this method, modelling a protein sequence of length > 150 residues can be a challenge. However, the *de-novo* design of peptides using the computer-aided parameterization offers one solution. Even, the *de-novo* protein design can be used to create small stable proteins that can bind to any specific therapeutic targets (Chevalier *et al.*, 2017). Another method, threading or fold recognition searches the protein structure template in a library with lowest possible energy for the query sequence. Homology modelling or comparative modelling uses the protein sequence identity between the input protein sequence and sequence of the template structure to construct the 3D structure. Hence better identity between query and target sequence will fetch a better modelled structure.

Plethora of review articles are available on strategies and challenges to protein structure prediction (Bonneau and Baker, 2001; Dorn *et al.*, 2014; Floudas *et al.*, 2006; Kc, 2016; Petrey and Honig, 2005).

Once the structure is modelled, it is always advised to check its quality using PROCHECK (Laskowski *et al.*, 1993), MOL-PROBITY (Chen *et al.*, 2010), VERIFY_3D (Bowie *et al.*, 1991; Luthy *et al.*, 1992) and WHAT_CHECK (Hoofst *et al.*, 1996). 3D structures of proteins open doors for various other structural analyses like functional annotation, interaction pathway analyses, target drug identification. Proteins in a cell cannot work alone and need interacting partners that can be a small molecule or biomolecule. Protein-protein interactions are mediated by hydrophobic interactions as well as H-bonds (De Las Rivas and Fontanillo, 2010). Understanding the importance of these interactions is vital in design and engineering of functional assemblies. The functional importance of the non-bonded interactions in assembly of biomolecular structures has been analyzed and firmly established through studies on DNA-protein (Mandel-Gutfreund *et al.*, 1998), RNA-protein (Wilson and Nierhaus, 2003), protein-protein (Singh *et al.*, 2003; Zondlo, 2010) and protein-ligand interactions (Panigrahi and Desiraju, 2007). Knowing the importance of these interactions, many algorithms have been developed over the years (Babu, 2003; Kumar *et al.*, 2014; Lindauer *et al.*, 1996; McDonald and Thornton, 1994; Tina *et al.*, 2007; Tiwari and Panigrahi, 2007).

Polysaccharides-Macromolecular Biopolymer

Classically, polysaccharides are defined as high molecular weight macromolecules composed of two or more monosaccharides that are connected by glycosidic bonds (Aspinall, 1985; Bochkov and Zaikov, 2016). Depending on the type of building units, polysaccharides may be classified as homosaccharides and heterosaccharides. Most polysaccharides are used as energy-storing units inside the living cells and tissues (Nonogaki *et al.*, 2000), while some of them are involved in cellular signaling (Tincer *et al.*, 2015) and in forming the protective outer membrane of living cells (Zhang *et al.*, 2016). It has some *in vitro* applications as well in pharmacy, textiles (Sanghi *et al.*, 2007) and nanomaterials (Lin *et al.*, 2012). Over the past two decades, numerous reviews and symposia have been published on the structure, metabolism and function of polysaccharides (Ramberg *et al.*, 2010; Srivastava and Kulshreshtha, 1989; Zong *et al.*, 2012). With the growing interest in this field, development of advanced tools and software for prediction of secondary structure of polysaccharides is becoming imperative (Pérez *et al.*, 2014). Most of these approaches are aimed at developing computational based techniques from NMR parameters of polysaccharides (Toukach and Ananikov, 2013).

Structural Features of Food Storage Polysaccharides

The three main food storage polysaccharides within the living cells are starch, cellulose and glycogen. A molecular genetics approach and 3D structure prediction methods have been chosen to determine the functional domain of the storage polysaccharides (Hostinová *et al.*, 2003). Sequence homology has also been applied for these purposes (Svensson *et al.*, 1989). Starch is formed when glucoses are linearly linked up by α 1–4 linkages (Fig. 13) (Brown and Kelly, 1993). Cellulose is mainly produced

Fig. 13 Subunit structures of some common storage and structural polysaccharides. All structures are created by using ChemDraw Ultra software. Rhodes, D., Lipps, H.J., 2015. G-quadruplexes and their regulatory roles in biology. *Nucleic Acids Research* 43, 8627–8637.

from the hydrated form of some bacteria (e.g., *Acetobacter Xylinum*) (Ross *et al.*, 1987) containing thousands of beta-D-glucopyranose units.

Glycogen is the multi-branched polysaccharides of glucose. It serves as a form of energy storage in humans, animals, fungi, and bacteria (Arrese and Soulages, 2010). There are two types of linkages, mainly 1–4 linkages are found in the straight part where as 1–6 linkages are found in the branched part. The straight part is helically twisted in nature and containing six glucose units per turn.

Structural Features of Chitin Polysaccharides

Structural polysaccharides are mainly involved in forming cell walls of different plants and animals. Chitin and cellulose both are the examples of structural polysaccharides. Chitin is a naturally abundant mucopolysaccharide (Sekiguchi *et al.*, 1994). It consists of 2-acetamido-2-deoxy- β -D-glucose through a β (1 $\rightarrow$ 4) linkage (Muzzarelli, 1973).

Polysaccharide 3D Structure Prediction and Analyses

Polysaccharides and their glycol-conjugates play an important role in cell-cell adhesion (Gribova *et al.*, 2011), inflammation (Jiang *et al.*, 2010) and immune activity (Yang *et al.*, 2009; Yongxu and Jicheng, 2008). Therefore secondary structure predictions of polysaccharides become a crucial thing in understanding the biological phenomenon (Dwek, 1996). Secondary structures possess regularities in various geometric and conformational parameters like glycosidic angles and specific patterns of H-bonds. Several computational techniques have been developed for analyzing the conformations of polysaccharides *in vacuo* (Wormald *et al.*, 2002). Monte Carlo methods (Peters *et al.*, 1993) and genetic algorithms (Nahmany *et al.*, 2005) have also been used for these purpose. Molecular dynamics simulations were carried out using GROMACS software (Van Der Spoel *et al.*, 2005) with OPLS-AA force field (Jorgensen *et al.*, 1996). Carb-builder is one of the software that is used to build the molecular models of complex oligosaccharides or polysaccharides (Kuttel *et al.*, 2016). POLY 2.0 is another open source software (Engelsen *et al.*, 2014). It can generate complex branched carbohydrates and polysaccharides structures using data from their optimized building mono-saccharides and glycosidic linkages. SWEET also serves the same purpose. It is a web-based software that quickly forms reliable three dimensional structures of polysaccharides from their preliminary sequence information (Bohne *et al.*, 1999). Advanced version of the SWEET only generates one of the conformations out of the manifold. Generated structure shows all the glycosidic linkages with reported variation of phi, psi and omega values. Sugar folding, a computer based tool is also used to predict the conformation of complex oligosaccharides in solution (Xia *et al.*, 2007). There is an effective software CASPER, used to determine the structure of the branched oligosaccharides and polysaccharides (Stenutz *et al.*, 1998). The CASPER program was developed for the analysis of the primary structures of oligosaccharides and for polysaccharides with repeating units. The approach is based mainly on NMR spectroscopy. Once the structure is modelled, we can visualize the secondary structures by SweetUnityMol, which is one of the specific computer graphics based software and can depict the complex interactions within polysaccharides (Pérez *et al.*, 2014).

Recent Advancement

A lot of polysaccharide structures have been elucidated from the crystallography in the last few years. Though the actual structure-function relationship is not yet established for many polysaccharides due to their diverse and complex structure. For the last three decades, besides the computer based tools, advanced NMR spectroscopy has also played an important role in determination of the structure of polysaccharides. A lot of advanced NMR techniques have been used, such as COSY (Lack *et al.*, 2007; Sinha *et al.*, 2010), NOESY (Fedonenko *et al.*, 2002; Larocque *et al.*, 2003; Linker *et al.*, 2001), TOCSY (Johnson and Pinto, 2002; Kjellberg *et al.*, 1998; Maciel *et al.*, 2008), HETCOR (Cescutti *et al.*, 1993) and NOE (Martin-Pastor and Bush, 1999; Michael *et al.*, 2002; Yamasaki and Bacon, 1991). Advancements in NMR methods with potential applications towards polysaccharide studies open a new area of research. Coarse grained molecular simulations (Bathe *et al.*, 2005; Wohler and Berglund, 2011) can also provide some new insights in this field.

Closing Remarks: How Close Are We?

Lack of enough number of 3D structures and presence of more number of atoms that can interact to each other, make the SSE prediction and assignment difficult for nucleic acids. In contrast to di-peptide, di-nucleotide has got more flexibility as they have seven back bone torsion angles compared to only three in di-peptide. For example, there is an exponential increase in the number of possible structures with increase in the length of RNA (Zuker and Sankoff, 1984). A nucleic acid chain with 100 nucleotides has more than 10^{25} possible secondary structures (Mathews, 2006). Further, the discovery of RNA thermometers in 1989 (Altuvia *et al.*, 1989), made things more complicated as it was found that certain types of sequences can be very sensitive to change in temperature.

For a given protein structure, there is not a consensus in identifying SSEs. Especially, the termini of SSEs are not defined uniformly. In general, they have an agreement of about 80%. Many less frequently occurring SSEs like π -helices and PPII-helices are not defined in clear cut way. In fact, none of the available algorithms can identify 2.2₇-helices. Same holds true for the prediction of SSEs for any input sequence, but the accuracy of their prediction is improving with the increase in the number of 3D structures of proteins. Are we able to design a desired protein structure with natural amino acids? Answer is not a perfect yes. Are we able to incorporate the enzymatic activities in a designed peptides or proteins? Though the answer to this question can be yes, it will be with a caveat: the activity is far less than that in the native protein. A lot of work has been done, but there is still a long way to go. For example, information on which amino acids favour 3₁₀ or π -helical conformations over α -helices, is still not clear. However, we are slowly and steadily reaching towards the goal and increasing number of 3D structures, as well as computational studies are playing a major role in understanding these features.

Biographical Sketch

Prasun Kumar received a Bachelor of Technology degree in Bioinformatics from SASTRA University. For his Ph.D. in molecular biophysics, he worked with Prof. Manju Bansal at Molecular Biophysics Unit, Indian Institute of Science. The main thrust of his graduate studies was to develop algorithms for the identification and analyses of various secondary structure elements in protein structures. His work on comprehensive *in-silico* analyses of commonly occurring, as well as less frequently observed helices like π and PolyProline-II helices in globular proteins provided more insights into the sequence-structure relationships. He has also worked on structural analyses of nucleic acids and contributed to the modifications of in-house programs NUPARM as well as NUC-GEN. Prasun is now a postdoctoral research associate in Prof. Derek N. Woolfson's group at University of Bristol, United Kingdom, where he is working on the development of algorithms and *de novo* design of coiled-coils with a focus on probing non-covalent interactions within these.

Swagata Halder, received a Master of Science degree in Chemistry from Bengal Engineering and Science University, Shibpur. She has done her Ph.D in Molecular Biophysics under the supervision of Prof. Chaitali Mukhopadhyay, Department of Chemistry in University of Calcutta. Her research work was based on "Effect of Glycosylation on the Protein Structure and Dynamics: Insights from Molecular Modelling". She has modelled and simulated various glycosylated proteins like legume lectin Soybean agglutinin (SBA) and some antifreeze proteins like Ocean Pout during her graduate research. The main focus of the study was to predict the atomistic details of protein-carbohydrate interactions which play important roles in molecular mechanism of some biologically relevant phenomenon. Swagata is now a postdoctoral fellow in Prof. Manju Bansal's research group at Indian Institute of Science, India. Her current research is on identification and characterization of RNA thermometers in bacteria by molecular dynamic simulations. She is also working on aggregation property of some disease related proteins in presence of DNA by Replica Exchange MD techniques.

Professor Manju Bansal carried out her doctoral research under the guidance of Prof G N Ramachandran at the Indian Institute of Science, Bangalore and worked on the triple helical structure of fibrous protein collagen. She received her PhD degree in 1977 and joined the faculty of IISc in 1982, where she is currently an INSA Senior Scientist and J.C. Bose National Fellow. She has been an Alexander von Humboldt Fellow at EMBL Heidelberg and Frei Univ Berlin, and a Senior Fulbright Fellow at UCSF, San Francisco. She was the founder-Director of the Institute of Bioinformatics and Applied Biotechnology, Bangalore and represents India on the Advisory Board of wwPDB. She has published more than 120 papers in International journals and mentored about 60 doctoral and graduate students. Dr. Bansal's research interests have primarily focused on relating protein and DNA sequences to their structures and function, by developing new concepts, computational algorithms and tools, particularly in the area of DNA promoter architecture. Supramolecular RNA Structures

Proteins are responsible for carrying out vital cellular functions achieved through the combination of self-assembly and conformational dynamics. The structural variability of protein (complex three-dimensional folded structures) underlies its ability in mediating almost all functions in living cells. With the discovery of small regulatory RNA (sRNAs) (Zamore and Haley, 2005) and the discovery of the catalytic ability of ribozymes (Altman, 1990), RNA emerges as a more versatile molecule than previously perceived. Similar to protein, RNA structure determines its function, but unlike protein, the secondary structure of RNA molecule provides more information regarding its tertiary folding; thus, promoting rational design of programmable and functional RNA supramolecular structures to be constructed (i.e., nanostructures of the size of 10 nm in dimension (Goodsell, 2004)).

The discovery of short RNAs' (which is 21–25 nt in length) role in regulating gene expression (Couzin, 2002) has sparked a strong interest in RNA molecules. In RNA interference, a short interfering RNA molecule (siRNA) forms base pair with a target region in mRNA, allowing a protein complex called RNA-induced silencing complex or (RISC) to attach and cleaves the target region (Hannon, 2002; Petersen *et al.*, 2006). Another short RNAs called microRNA (miRNA), generated from an enzyme named Dicer that cleaved non-coding RNAs (i.e., RNA that do not code protein), binds imperfectly with the target region in mRNA (forming a bulge) to prevent the translation machinery from accessing this target region (Zamore and Haley, 2005). In addition to these short RNAs, another complex folded RNA domain called riboswitches also play a role in gene regulation. Riboswitches sense the presence of specific metabolites and harness their conformational switching to activate the gene-control mechanisms in preventing the production of protein (Mandal and Breaker, 2004; Nudler and Mironov, 2004).

RNA nanotechnology focuses on the engineering of functional and customizable supramolecular RNA structures as molecular devices utilizing the self-assembly principle of nucleic acids, reviewed in Jaeger and Chworos (2006); Guo (2010); Shu *et al.* (2014); Li *et al.* (2015); Jasinski *et al.* (2017). Advances in RNA nanotechnology have enabled the development of various RNA nanoparticles in nanomedicine, detailed explicitly in Jasinski *et al.* (2017). RNA nanoparticles have been developed as an alternate platform for targeted therapeutic delivery mechanism in the form of RNA aptamers (Esposito *et al.*, 2011; Shigdar *et al.*, 2011; Rockey *et al.*, 2011; Guo *et al.*, 2012; Thiel *et al.*, 2012; Kang and Lee, 2012; Zhou *et al.*, 2012; Sundaram *et al.*, 2013), as Ribozymes-based therapeutic strategy (Mulhbachter *et al.*, 2010; Shu *et al.*, 2011), as gene expression regulator through utilization of various Riboswitches (Suess and Weigand, 2008; Serganov, 2009; Berens *et al.*, 2015) and RNA interference therapy (Haque *et al.*, 2012; Ye *et al.*, 2012; Shu *et al.*, 2015; Lee *et al.*, 2015; Roh *et al.*, 2016).

Instead of mimicking the methodologies commonly associated with synthetic DNA nanostructures (commonly known as "DNA Origami"), RNA nanostructures are able to follow a more natural suprastructures formation. This can be achieved through the multi-self-assemblies of natural occurring RNA motifs (i.e., optimization of kinetic foldings and thermodynamic requirement based on combination of existing RNA motifs). The conceptualization of the desired nanostructures is rather straight-forward since the design will be based on a dictionary (or database) of well-characterized RNA motifs. This tutorial highlights the various methodologies for constructing supra-molecular RNAs and presents a generic computational protocols to support the in-silico construction.

Properties of Ribonucleic Acids

Nucleic acids are macromolecules that play an important role as information carriers in cells. Two types occur, ribonucleic acids (RNA) and de-oxyribonucleic acids (DNA), which are named after the structure of a sugar component in these molecules. RNA and DNA are typically long linear polymers that consist of a large number of monomers taken from a set of four different nucleotides (C, G, A, and T or U for RNA). The sequential order in which these bases are interlinked in the nucleic acid molecule represents information. RNA has the task of transmitting information within the cell, while DNA transmits information from generation to generation. The genetic information is encoded in a dimer of two complementary nucleotide chains ('single-stranded' DNA or ssDNA) which upon self-assembly assumes the well known double-helical structure ('double-stranded' DNA or dsDNA). DNA is well suited as carrier of genetic information because of its energy degeneracy with respect to the sequential order of the nucleotides. The properties of RNA molecules are more dependent on the sequence of nucleotides and as a consequence RNA takes on additional roles in the cell aside from representing information.

Within the RNA hierarchical framework, stacking and Watson-Crick base pairing between complementary nucleotides (canonical base pairing) trigger folding and assembly of RNA primary sequences into secondary structures (hairpin loops, bulges, internal loops and multiloops) as depicted in Fig. 1. The hydroxyl group (-OH) at the 2'-carbon in ribose is not present in deoxyribose (Berg *et al.*, 2003). The consequence of this structural difference is twofold. DNA is considerably more stable against hydrolysis and forms more compact double strands, while RNA has more conformational flexibility (Bloomfield *et al.*, 2000). The

Fig. 1 RNA Structural Motifs. The intra-molecular binding creates RNA motifs such as bulges, internal, and hairpin loops. RNA molecule can forms inter-molecular binding, which produces junctions. From 2-way or kink-turn, the commonly used 3-way or 3WJ in nanoparticles fabrication, four-way (shown here), and available up to 9 way junctions), kissing hairpins and pseudoknot. There are also GNRA-Loop Receptor, Triple helical scaffold and G-Quadruplex motifs that are common in RNA suprastructure constructions. Reproduced from Jasinski, D., Haque, F., Binzel, D.W., Guo, P., 2017. Advancement of the emerging field of RNA nanotechnology. *ACS Nano* 11 (2), 1142–1164.

2'-hydroxyl group locks the ribose sugar into a 3'-endo chair conformation. It is structurally favorable for the RNA double helix to adopt the A-form which is 20% shorter and wider than B-form DNA helices. The A-form RNA helices are thermodynamically more stable than the B-form DNA helices (SantaLucia-Jr, 1998). However, the 2'-hydroxyl group permits RNA to be susceptible to nuclease digestion which limits RNA stability in-vivo.

For a given RNA sequence, there is often a diverse set of secondary structures it can fold into. Which structure is favored will depend on the physico-chemical environment of the molecule, for example, the presence or absence of substrates or ions. In addition, the presence of non-canonical base pairs can contribute significantly to RNA folding. Affecting the rigidity and thermodynamic stability of RNA secondary structures (Mathews and Turner, 2006). Conversely, a diverse set of sequence configurations can yield a particular secondary structure (Draper, 1996; Zuker, 1989) through energy minimization model. Subsequently, interactions among secondary structure motifs lead to the formation of a tertiary structure which in some cases entails functionality (Fig. 2).

Compared to the folding of protein, the amount of energy released during the formation of RNA secondary structure is much larger than the energy required during the formation of its tertiary structure. On its own, RNA secondary structure is quite informative. Long helices that are present in the secondary phase are most likely preserved in its tertiary structure. This, therefore provide a reasonable prediction of the basic form and relative positioning for some elements in the tertiary structure (Higgs, 1995). Determining the secondary structures is an integral element of predicting the tertiary motifs.

A. via Hand-in-Hand**B. via Foot-to-Foot****C. via RNA Architectonics (tectoRNA)**

Natural occurring RNAs have been identified and characterized using NMR and crystallographic atomic structures (Leontis *et al.*, 1995; Moore, 1999). Natural occurring RNAs provide a definitive blueprint in the design of supramolecular structures through the representation of the sequence to structure relationship (i.e., natural occurring structures are encoded in naturally conserved sequences). These natural motifs provide geometry information of helical elements, and mediate stereochemically precise and readily reversible tertiary and quaternary interactions (Jaeger and Chworos, 2006). This information allows RNA supra-structures to be engineered with relatively accurate approximation supplemented by the secondary structure prediction. In terms of engineering supra-molecular RNA structures, this hierarchical folding state has to be observed closely to avoid kinetically trapped misfolded states, which disrupt the formation of the intended structures.

Techniques for Constructing RNA Nanostructures

A variety of supramolecular RNA structures (also known as RNA nanoparticles) have been successfully fabricated using various self-assembly approaches. In depth reviews of these methodologies are available in Li *et al.* (2015); Jasinski *et al.* (2017). This section provides a description of these construction methodologies, and we strongly recommend readers to refer to the references that are supplemented in each method for further understanding of the self-assembly mechanisms.

Via Hand-In-Hand Interactions

The strategy utilizes RNA loop elements as inter-RNA mounting dovetails (Fig. 3(A)). Incorporating these internal RNA loops eliminates the need for external dovetail elements. The design principles are exemplified by the structural features of the packaging RNA (pRNA) derived from bacteriophage *phi29* (Guo *et al.*, 1987). Through inter-locking loop interactions between different pRNAs, dimers, trimers, tetramers, pentamers, hexamers, and heptamers have been created (Guo *et al.*, 1998; Shu *et al.*, 2004, 2013a,b). Adaptation using non-covalent loop-loop contacts based on RNAI/III kissing-loop complex have been used to build RNA nanorings (Yingling *et al.*, 2007; Grabow *et al.*, 2011), which are thermostable, ribonuclease resistance and capable of delivering RNA interference modules.

Via Foot-to-Foot Interactions

Extending the 3' end of pRNA monomer with a single stranded palindrome sequence promotes self-assembly of two pRNA molecules. The complementarity of the palindrome sequence bridges the two foot orientations (i.e., foot-to-foot interaction) (as depicted Fig. 3(B)) (Shu *et al.*, 2004, 2013a,b). Construction of RNA hexamers, octamers, decamers, and dodecamers utilizing palindrome sequence to bridge RNA motifs, or scaffolds have been reported (Li *et al.*, 2015). Combination of both hand-in-hand and foot-to-foot interactions has been reported to construct pRNA array (Shu *et al.*, 2004). Fusions of sticky-end cohesion with foot-to-foot interactions were also reported to construct RNA nanoprisms in Hao *et al.* (2014) through the re-engineering of pRNA molecule.

Via Rational Design With Natural RNA Motifs

The discovery of natural occurring RNA molecules provides a definitive template in constructing RNA supramolecules, where precise structural information and structure to sequence relationship are defined through various RNA motifs. Rational design utilizing stable RNA motifs (e.g., kissing loops, dovetails, pseudoknots, kink turns, and multiway junctions) has produced exciting RNA supramolecule structures (Leontis *et al.*, 1995; Leontis and Westhof, 2003; Petrov *et al.*, 2013). Larger, more complex, and extraordinary stable natural motifs, such as *phi29* motor of pRNA (Guo *et al.*, 1998; Zhang *et al.*, 2013), tRNA (Severcan *et al.*, 2010), 5S RNA (Shu *et al.*, 2011), and others (Grabow *et al.*, 2011) have been used to form synthetic RNA supramolecules (Dibrov *et al.*, 2011; Shu *et al.*, 2013b; Jasinski *et al.*, 2014; Khisamutdinov *et al.*, 2014). A popular RNA motifs exploitation is the robust pRNA-3WJ motif. The extended work of hybrid strategy utilizing *phi29* pRNA-3WJ motifs for nanostructures fabrication with precise size, 3D architecture and container, RNA Dendrimer and co-transcription and inter-cellularly multifunctional nanostructures have been reported (Jasinski *et al.*, 2017).

Via RNA Architectonics (Tectona)

RNA tectonics focuses on the modularity of RNA molecules (Jaeger and Chworos, 2006). The strategy exploited the ability of RNA structures to decomposed and reassembled into a new modular RNA structure (Ref. Fig. 3(C)). Through the inversion of the

hierarchical folding (from tertiary to secondary structure to primary sequence), outline of the supramolecular RNA structures encompassing the tertiary motifs, secondary motifs, intra and inter-molecular interactions, and conserved sequences can be extracted. Thus, providing the geometry and self-assembly phases necessary to design the supramolecules. With the availability of Structural Classification of RNA (SCOR) (Klosterman *et al.*, 2004; Tamura *et al.*, 2004), nucleic acids databases (NDB) (Berman *et al.*, 1996), and the RNAjunction database (Bindewald *et al.*, 2008b), there exists a large number of candidate tectoRNA motifs. Readily configured as supramolecules through semi-rigid double helical bindings as exemplified in Westhof *et al.* (1996); Jaeger and Leontis (2000); Chworos *et al.* (2004); Shu *et al.* (2004); Nasalean *et al.* (2006); Dibrov *et al.* (2011); Ishikawa *et al.* (2013); Yu *et al.* (2015).

Via RNA Origami

The field of DNA nanotechnology leverages on the DNA complementarity self-assembly guided by the canonical Watson-Crick interactions (G-C and A-T base pairing), and structural rules (based on Holliday junction) to create DNA nanostructures (Lin *et al.*, 2006; Feldkamp and Niemeyer, 2006; Seeman, 2007, 2010; Lin *et al.*, 2009). These governing rules have resulted into various DNA nanoscaffolds (Brucalé *et al.*, 2006; Erben *et al.*, 2007; Andersen *et al.*, 2008; Aldaye *et al.*, 2008; Zimmermann *et al.*, 2008; Bhatia *et al.*, 2009; Licata and Tkachenko, 2009) with extensive functionalities formed through self-assembly of DNA subunits called “DNA tiles”. A different approach for DNA “origami” was presented in Rothmund (2006), where by a long stranded DNA is “stapled” into complex geometry using short complementary DNA strands. In this context, the less hierarchical and directed nature of DNA folding (i.e., double-stranded formation) are better suited for such approach, exemplified by the fabrication of various DNA supramolecules (Dietz *et al.*, 2009; Ke *et al.*, 2009; Douglas *et al.*, 2012; Zadegan *et al.*, 2012). The interpretation of RNA “origami” utilizing the short “stapled” approach is presented in Endo *et al.* (2014), where long ssRNAs are folded into rode-like structures using short RNA staples through in-vitro transcription of dsDNA scaffold and DNA staple templates. Further expansion of the “ssOrigami” method for single-stranded RNAs are discussed in Han *et al.* (2017).

Computational Methods of Constructing RNA Supramolecules

Despite the various strategies of constructing RNA supramolecules (as presented in Section “Techniques for Constructing RNA Nanostructures”), in actuality, the design and construction of these supramolecular structures relies heavily on manual assembly and fine tuning. Manual design has significant impact on the time and cost incurred to engineer these functional supramolecules, and taking into consideration the drive to produce more cost effective, and high demand for more complex structures, autonomous computational pipelines/protocols are a must. The general approach to RNA nanotechnology has now adapt to allow computational and folding prediction as one of the steps in the construction, immediately following the conceptualization as discussed in Guo (2010).

In contrast to protein, there exist well established computational tools that can aid in the secondary structure prediction and sequence design of RNA molecules. Tools such as *mfold* and *DINAMelt* (Zuker *et al.*, 1991; Zuker, 2003; Markham and Zuker, 2005), the *Vienna RNA Package* (Hofacker *et al.*, 1994), *RNAstructure* (Mathews *et al.*, 2004), *RNAsoft* (Andronescu *et al.*, 2003) and *RNAshapes* (Steffen *et al.*, 2006) are some of the most common and well-known in the prediction of RNA secondary structure. Secondary structure prediction is supplemented with sub-optimal prediction (Zuker, 1989; Wuchty *et al.*, 1999), which allows further determination of how well-defined the lowest free energy structure is, and at the same time highlight weak base-pairing positions that are present in a structure.

Secondary structure prediction has also been extended to includes interacting molecules (Andronescu, 2003; Dimitrov and Zuker, 2004; Muckstein *et al.*, 2006; Andronescu *et al.*, 2005; Bernhart *et al.*, 2006; Bindewald *et al.*, 2011). In the context of engineering RNA supramolecules, understanding the interactions between multiple RNA strands is essential in order to allow the evaluation of their binding compatibility to take place. The secondary structure prediction for interacting RNA molecules also quantifies the probability of homo-dimer formation (Dimitrov and Zuker, 2004). The relative probability of inter-molecular and intra-molecular binding is another critical aspect to consider. To arrive to the desired supramolecular structures, it is important that the base pairing within each molecule binds stronger than any possible intermolecular binding involving other molecules in the solution, or vice-versa depending on the intended function and structural constraints.

Although definitive sequence to structure mappings are available for natural occurring RNA motifs, the exploitation of multi-motifs self-assembly (following the previously discussed strategies) requires synthetic modification to the existing sequence. Therefore, consideration for the inverse folding prediction must be taken. The inverse folding problem involves designing RNA sequences that fold into a specified secondary structure (Schuster, 2006). By solving this problem, it allows for supramolecular structures to be artificially designed based on specific structural constraints and functionality. The three common inverse prediction tools are *RNAinverse* from the Vienna package (Hofacker *et al.*, 1994), *RNAdesigner* (Andronescu *et al.*, 2004) from the *RNAsoft* package (Andronescu *et al.*, 2003) and *INFO-RNA* (Busch and Backofen, 2006). In test cases of more than 150 nt artificially and naturally occurring RNA molecules, both these tools *RNAdesigner* and *INFO-RNA* produce encouraging results with both performs much better than *RNAinverse* overall (Andronescu *et al.*, 2004; Busch and Backofen, 2006; Zadeh *et al.*, 2011).

Since, the characterization and categorization of known RNA motifs plays a major role in constructing RNA supramolecular structures, the curation of RNA motifs into searchable databases is a powerful tool for the computer aided design pipeline (Jaeger and Chworos, 2006; Bindewald *et al.*, 2008a,b). To facilitate the construction, information related to the conserved sequences and

Fig. 4 The computational pipeline for engineering RNA supramolecular structures. The conceptualization produces hypothetical module of the structure that will undergo structural configuration and refinement before candidates are generated for lab verification.

structures mapping is key (i.e., to reduce the run time needed during inverse folding prediction and to ensure workability in the laboratory). This, determines the compatibility of multi-motifs self-assembly and other structural manipulations (Jaeger and Chworos, 2006). These databases classify RNA structures by function, tertiary interactions (geometry), as in the Structural Classification of RNA (SCOR) and nucleic acid database (NDB) (Berman *et al.*, 1996; Klosterman *et al.*, 2004; Tamura *et al.*, 2004). One of the most commonly associated databases for RNA supramolecular construction is RNAJunction (Bindewald *et al.*, 2008b). RNAJunction consists of approximately 13,000 junction motifs and kissing loops derived from the Protein Data Bank (PDB). These motifs are clustered into 2-way or 2WJ (bulge and internal loops) up to 9-way or 9WJ junctions. RNAJunction database also includes the basis of documented geometries and recurring base- and tertiary- interactions of these motifs.

In addition to the databases, there are various design tools that can aid the design of RNA supramolecular structures in three dimensional workspace (Bindewald *et al.*, 2008a; Martinez *et al.*, 2008; Jossinet *et al.*, 2010; Xia *et al.*, 2010). One such tool is NanoTiler (Bindewald *et al.*, 2008a). NanoTiler generates candidate RNA motifs from the RNAJunction database or similar databases. These candidate motifs can be assemble through a variable length pre-defined RNA helices. The tool also allows sequence conservations, to ensure conformity of the tertiary foldings. NanoTiler can function similar to a design studio, where custom candidate motifs can be generated with various structural modifications subjected to the plausible characteristic of natural RNA folding principles, and it is also capable of producing RNA primary sequences to match these custom designed motifs. These sequences have good agreement to be realized in the laboratory as exemplified in the construction of RNA supramolecules depicted in Bindewald *et al.* (2008a).

In addition to NanoTiler, we have RNA2D3D (Martinez *et al.*, 2008). RNA2D3D allows for rapid three dimensional modeling of the supramolecular structures using the primary sequence and secondary structure pairing information. It also provides adjustment tools for

structural modification; to avoid steric clashes and optimize the thermodynamics. RNA2D3D capacity to integrate multiple motifs into a draft model of supramolecule structures (through default kissing-loop interactions) is essential in providing immediate feedback to the user. Alternatively, there are various general purpose molecular modeling packages, such as the Chimera (Pettersen *et al.*, 2004), and pyMol (Grell *et al.*, 2006), which are capable in modeling RNA supramolecular structures. However, due to its generic form, these tools lack the specific knowledge-based of RNA foldings; but offer flexibility for integration with other customizable pipelines.

Using the strategies (discussed in section “Techniques for Constructing RNA Nanostructures”), a generic computational pipeline can be established as depicted in Fig. 4. The implementation of the pipeline is subjected to the level of depth in the conceptualization phase as suggested in Afonin *et al.* (2014). This level can either be; whether (i) candidate motifs are already identified (or partially identified) or, (ii) a discovery to identify suitable motifs is needed. Key in the pipeline is the conceptualization phase. During this phase, the identification of the desired structures and functions are established. This includes consideration on the physico-chemical environment, size, complexity, geometry, restriction on sequences and relevant factors that should be based on extensive RNA folding knowledge base. The conceptualization will either produced constraints for immediate structural assembly and modification – For (i) (also referred as “Draft Secondary Structure” in Afonin *et al.* (2014)), or a set of criterion that can be used as search parameters in motif discovery - for (ii) (also referred as “Connectivity Rules” in Afonin *et al.* (2014)). Either way, both of these findings are essential and will be adapted as specification sheet during the construction phase.

Next, the selection of strategy for multi-motifs self-assembly. Although categorically different, these strategies are in-fact overlap (Afonin *et al.*, 2014). A closed design principle (i.e., where the self-assembly motifs are manually pre-determined) promotes a top-to-bottom optimization, where hypothetical supramolecular structures are decomposed into motifs with inter-molecular reactions reassembly components based on the “best-fit” strategy conforming to the selected motifs. In contrast, an open system, where only connectivity rules are defined (case (ii)), the bottom-up optimization is preferred. Combinatory search of the databases to find candidate motifs is executed and inter-molecular assembly recommendations would be made based on the “best-fit” strategy depending on the motif compatibility scores. During these process of optimizing the formation of structures, RNA 3D modeling programs such as NanoTiler and RNA2D3D are important. These tools provide immediate feedback on the compatibility of self-assembly between the suggested motifs.

Structural optimization follows next. The summary of the protocols are presented in Shapiro *et al.* (2008). The NanoTiler optimization protocol is described in Algo. 1. Interactions with NanoTiler are permissible via a graphical user interface or scripting language. NanoTiler allows optimization to be performed on motif placements and helix distortion to improve on the “best-fit” score. The bottom-up protocol is described in Algo. 2, and requires both RNA2D3D and NanoTiler. RNA2D3D allows interaction rules between multiple building blocks to be included (i.e., “Connectivity Rules”) and rapidly generates the approximate supramolecular structure rendering. NanoTiler, in this instance acts as a refinement module to improve on the configuration of the selected motifs.

As recommended by [Shapiro *et al.* \(2008\)](#), the designs are subjected to molecular mechanics and molecular dynamics inspection to ensure positive results in the laboratory. Output of the pipeline will then undergo the fabrication process. Two strategies for fabricating RNA supramolecular structure is discussed in [Jaeger and Chworos \(2006\)](#). The first approach is a single step assembly, in which all the sequences (i.e., primary sequence of the RNA motifs) are mixed together and assembled in a solution through a slow annealing process. The second strategy involves stepwise hierarchical self-assembly. Smaller sub-units are separately assembled before all these motifs are mixed together to form the supramolecular structures. Conceptually similar to the hierarchical folding property of RNA molecule.

Conclusion

RNA supramolecule constructions involves intra/inter-molecular assembly of various RNA motifs. Understanding the folding of RNA motifs is essential in ensuring the conformity of the structure and functionality. The flexibility of RNA folding, allows variations (or meta-stable states) to exist within a small free energy value difference. This variability is further compounded when multiple motifs assembly are involved. Despite the presence of prediction tools to aid in the construction of RNA supramolecular structures, accurate prediction of tertiary and quarternary motifs remains a challenge. Prediction tools specific for tertiary structures are yet to be explored. Within this context, inverse folding involving multiple strands is necessary.

On the computational aspects, more enhancements are needed. For instance, the construction of supramolecule must consider a combination of an increased number of RNA motifs to improve on the demand for more complex multi-functional RNA structures. Accuracy in size, structural and function of these supramolecules are aspect that should be addressed during the design phase. Perhaps, a better combinatorial search with sufficient parameterization can help in identification of suitable RNA motifs, and a deep learning methodology can be incorporated in understanding the geometry and self-assembling mechanisms of complex natural occurring RNA supramolecule, thus, providing valuable insights into a better strategy of constructing RNA supramolecule. This will greatly benefit the field of RNA nanotechnology especially towards the design of a more complex and advanced supramolecule applicable towards the realization of nanomedicine.

Introduction

Tertiary interactions, such as those mediated by hydrogen bonds, serve as stabilization elements of RNA 3D structure (Krasilnikov and Mondragón, 2003; Nissen *et al.*, 2001). To date, numerous examples of tertiary interactions have been reported and these can easily be browsed via resources such as the RNA 3D Hub (Leontis and Zirbel, 2012), InterRNA (Appasamy *et al.*, 2015), NCIR (Nagaswamy *et al.*, 2002), SCOR (Tamura *et al.*, 2004), RNAJunction (Bindewald *et al.*, 2007), RNA 3D Motif Atlas (Parlea *et al.*, 2016) and RNA Bricks (Chojnowski *et al.*, 2014). Tertiary interactions that are highly conserved can be considered as 3D or tertiary motifs.

The capability to predict RNA-RNA interactions is of even more importance given recent depositions of large assemblies of the ribosomal subunits with reasonably high resolution (Prokhorova *et al.*, 2017; Almutairi *et al.*, 2017; Tereshchenkov *et al.*, 2018). With high-resolution structures, the intricate atomic level interactions within the RNA's 3D structure can be adequate for structural analysis that can provide details of functional mechanisms (Koizumi *et al.*, 2016). Tertiary interactions within the RNA structure are biologically significant from various aspects. In a recent study on viroid RNA, the 3D base motifs are important factors for function, viroid infection and viroid genome evolution (Wang *et al.*, 2018). In addition, 3D structure of RNA has also shown to be conserved despite extensive sequence divergence (Capriotti and Marti-Renom, 2010). RNA tertiary motifs also provide specific transcriptional regulation together and may have therapeutic purposes in diseases (Huang *et al.*, 2015). The 3D structure of messenger RNA (mRNA) is also crucial in regulating the production of encoded proteins in addition to controlling and modulating synthesis and function of proteins (Mauger *et al.*, 2013).

There are variations as to what is defined as an RNA 3D motif. Here, we specifically discuss RNA base motifs that we define as a pattern of base arrangements that are annotated repeatedly in different locations either in the same RNA structure, or in different RNA molecules. Although there is a requirement for similarity in the 3D arrangement of the bases to be considered a motif, an alignment at the 1D sequence level is not required. In this article, we focus on computational methods that are able to identify base motifs and base-base interactions in the 3D structures of RNA.

RNA 3D motifs can be classified based on properties arising from the conformation of the RNA backbone and base pair interactions. Examples of conformational motifs include kink-turns, tetraloops, hook-turns, π turns, Ω turns and α loops (Klein *et al.*, 2001; Woese *et al.*, 1990; Szép *et al.*, 2003; Wadley and Pyle, 2004). However, for base motifs or base-base interactions, the arrangement similarities of the bases in 3D space are used for classification.

Background

Hydrogen bonds play crucial roles in the structures of biological macromolecules. The role of the hydrogen bond in protein structures is well recognized – an excellent example of their contribution towards orderly maintenance of 3-D structure is their core structure stabilization contributions in protein secondary structures. For example, the amino group nitrogen in an alpha helix backbone is the donor atom for a carbonyl group. In DNA, the two hydrogen bond interactions for A-T and the three hydrogen bonds between G-C that hold together the two strands of DNA in a double helix conformation as first described by Watson and Crick (1953) have become canon. In RNA structures, the base components of the nucleotides are also able to hydrogen bond in the canonical Watson-Crick arrangement. Additionally, the more diverse conformations that an RNA structure is able to fold into allow for the bases to interact in a plethora of arrangements that in turn result in a diverse array of base pairing arrangements as reported by Tinoco *et al.* (1973) as RNA are generally single-stranded; hence, less restricted to double helical conformation compared to DNA.

The work of Tinoco *et al.* (1973) expanded the repertoire of possible base pairings by considering other base interaction interfaces additional to the Watson-Crick interface (such as the sugar and Hoogsteen edges) and different geometries (such as the reverse Watson-Crick base pair). These additional base pair arrangements were; thus, termed non-canonical interactions that did not conform to the AT GC hydrogen bonding rule described by Watson and Crick (1953) in addition to possibly deviating from the ratio of Chargaff's rules (Chargaff, 1951) which is applicable to DNA content.

It became clear that these non-canonical interactions were not mere rare exceptions to the rule through work, such as the NCIR database (Nagaswamy *et al.*, 2002) by Fox and co-workers that catalogued a large number of non-canonical hydrogen bonded base interactions found in RNA structures reported in literature. Among the interactions in NCIR were arrangements that extended beyond simple base pairings to interactions consisting of three to five bases (see "Relevant Website section"). An extensive, manually curated literature sourced catalogue such as NCIR (Nagaswamy *et al.*, 2002); although useful, would not be able to provide an overview or proper accounting of the breadth of interactions that can probably be found in the RNA structures currently available in the PDB (Berman, 2008).

The increasing number of RNA structures in the PDB signalled the requirement for accurate computational means of identifying base interactions and the motifs they partake in. The ability to identify such base interactions and their locations in the 3D structure can be an important contributor in the function prediction or determination process. The increase in the number of RNA structures in the PDB such as the more recently available entries for ribosomal subunits (e.g., PDB ID: 6CFK), riboswitches (e.g., PDB ID: 6BFB), ribozymes (e.g., PDB ID: 5V3I), non-coding transcripts (e.g., PDB IDs: 5LYU, 5LSN) that are associated to human diseases ranging from cancer to infections are ripe targets for analysis of their base interactions in order to elucidate atomic level mechanistic details that can lead to potential therapeutic applications (Dasgupta *et al.*, 2017; Martinez-Zapien *et al.*, 2017; Podbevšek *et al.*, 2018; Rizvi *et al.*, 2018; Tereshchenkov *et al.*, 2018).

The computational analysis of RNA structures, specifically the interactions between and within RNA structures is not a new endeavor. However, due to the more recent availability of an increasing number of high resolution RNA structures, including very large complex assemblies, the computational analysis and comparisons of these structures in bulk is a nascent field that have the potential to be developed into pipelines to mine and develop RNA molecules as targets for therapeutic applications.

At this point, it must be made clear that an RNA base motif can consist of an arrangement of bases that are independent of their manner of hydrogen bonding. Nevertheless, using hydrogen bonds to define a motif is advantageous as there are clear definable parameters that can be calculated and these can also be used to differentiate different motifs that are otherwise visually similar.

The availability of high resolution RNA 3D structures enable the study of the basic interactions that stabilize the folded RNA molecule. In the early yeast tRNA structure, a network of hydrogen bond interactions was observed to run through most of the molecule with the exception of the exposed amino-acid and anticodon stems (Ladner *et al.*, 1975). Interaction networks in structured RNAs are therefore expected to feature prominently as a collective factor in stabilizing RNA structures. Among the interactions that can be found in such networks as listed by Lescoute and Westhof (2006) are: (i) phosphate-phosphate contacts mediated by water molecules or positively charged cations; (ii) phosphate-sugar hydrogen bonding usually mediated by the 2'-hydroxyl group; (iii) sugar-sugar hydrogen bonding interactions; (iv) base to phosphate or base to sugar hydrogen bonding; (v) base to phosphate or base to sugar stacking interactions; (vi) base to base hydrogen bonding interactions; (vii) base to base stacking interactions (Lescoute and Westhof, 2006).

Descriptions and Nomenclature of Base-Base Interactions

The base component of a nucleic acid can be divided into three edges: (i) the Watson-Crick face which is involved in the canonical Watson-Crick interactions, (ii) the sugar edge on the side of the glycosidic bond and (iii) the Hoogsteen edge (for purines) and CH edge (for pyrimidines) which are on the opposite side of the sugar face. Non-canonical base-base interactions therefore involve hydrogen bonding interfaced by one non-Watson-Crick base edge. Another type of non-canonical interaction may also occur which however involves the canonical Watson-Crick edges and was proposed by Francis Crick as the wobble-hypothesis (Crick, 1966). The orientation of bases to each other in RNA structures is not as easily described as can be done in DNA. The conformational diversity of RNA results in numerous other opportunities for bases to interact via non-canonical interactions as previously stated.

One method that can be used is to name the interactions based on the hydrogen bonding present. However, this is not as systematic nor does it provide an easy and immediate mental picture of the interaction. A nomenclature and classification system was proposed by Leontis and Westhof (2001) that enabled the diversity of possible base-base interactions to be better described. The basis of this nomenclature involved describing the base edges involved in the interaction in addition to the orientation of the glycosidic bond of one base to the other. We therefore propose that when descriptions of the arrangements are required, the Leontis and Westhof be used for uniformity and consistency.

Systems and/or Applications

Eleven servers that were found in the literature were compared for their utility in annotating base motifs or specific base-base interactions in RNA structures (Tables 1 and 2). The capacity of these different servers to find different types of base motifs and base-base interactions result in there being no single one stop solution for RNA structure annotation needs. These resources however complement each other in two ways – by using different methods for the searching and annotation and by covering different types of motifs that can be searched for and annotated. In general, all servers are able to accept as input either an existing PDB structure as a PDBID input or via an upload of the structure to be queried. Another feature shared by all the servers is the capability of providing visualization of the search output and making these output files available for downloads.

Analysis Approach and Utility of Base Arrangement Annotation

There are also a very limited set of tools that specifically annotates base arrangements or base-base interactions. In this analysis approach section, we compare and integrate these tools to those that take into account the folding of the RNA molecule into its substructure components, thus the services listed in Tables 1 and 2 do not necessarily carry out base motif and base interaction

Table 1 A listing of the eleven web servers and their URLs that can be used for annotating 3D motifs in RNA structures

Web server	URL
NASSAM	http://mfrlab.org/grafss/nassam

SETTER	http://setter.projekty.ms.mff.cuni.cz

annotation specifically. This enables expanding the discussion into how such tools can be used together to extract the most amount of information from an available RNA 3D structure.

In perhaps the majority of cases needing annotation of base arrangements in an RNA structure, the investigator starts with a newly solved structure, usually determined by X-ray diffraction. Tools that enable such structures to be annotated can thus provide a reference point for the investigator during analysis and visual inspection, especially for RNA structures that may involve complex interactions such as the ribosomal subunits. Unlike the redundancy often seen for sequence analysis programs, those that analyse at the structural level implement different approaches and were designed to find different targets thus resulting in the various servers being complementary to each other.

As an example, submitting a structure to the NASSAM server can provide a reference map for the investigator to identify known motifs. However, submitting the same structure to RAG-3D will retrieve a different set of results related to conserved topology that were not covered by NASSAM. The majority of these services annotate the RNA structure using a reference database thus limiting searches to known motifs and interactions.

In order to enable novel motif discovery, algorithms that are not dependent on a reference dataset need to be used. One method of discovering novel motifs would be to compare structures in order to look for unreported similar base arrangements or interactions present in multiple structures that may signal novelty. Such structure to structure annotations are possible by services such as ARTS and COGNAC, while some others actually require two or more structures as the input, such as RCLICK (see [Table 3](#)).

The use of hydrogen bonding patterns can also help differentiate between patterns. Subtle changes in the hydrogen bonding networks in the same structures that have undergone mutations or have been solved (crystallized) under different conditions can be used to identify structural shifts resulting from changes in the interactions between the bases. Furthermore, a highly hydrogen bonded grouping of bases that are repeated in different structures can imply that it may have functional or structural stabilization roles. Annotating such base interactions can thus be another means of identifying novel motifs.

Since most of these programs search and annotate an actual occurrence as opposed to being a prediction, what remains for the user to determine is how much the annotation conforms to the intended query. It is still possible to identify novel 3D motifs from such searches because the retrieved hits may deviate from the original query and may represent a yet unreported base arrangement. This was demonstrated by [Firdaus-Raih *et al.* \(2011\)](#) using the NASSAM program.

RNA structure annotation programs can also be used as a means of high-throughput structure annotation. The InterRNA database is an example of how the NASSAM and COGNAC algorithms were used to annotate high resolution RNA structures in the PDB ([Appasamy *et al.*, 2015](#)). The RNA 3D Motif Atlas is the result of annotating a representative set of RNA 3D structures using FR3D ([Sarver *et al.*, 2008](#)), which is available as the WebFR3D service. The DARTS database ([Abraham *et al.*, 2008](#)) is derived from structural comparisons using the ARTS program.

Although structural genomics level approaches for RNA chain containing structures have never been attempted, these tools will allow for rapid and systematic annotation for the output of such projects. Due to the different but complementary nature of the available services, selection of the correct analysis program will depend on the objectives of the investigator.

Illustrative Example(s) or Case Studies

In order to demonstrate the RNA structure annotation process, specifically that of base motifs and base interactions, we have used the structure of a T box riboswitch (PDB ID 4MGN) ([Grigg and Ke, 2013](#)) as a query that was submitted to the services listed in [Table 1](#). For services where a minimum of two structures needed to be submitted, the structure of another T box riboswitch (PDB ID 4LCK) ([Zhang and Ferré-D'amaré, 2013](#)) was also provided. The differences in the types of output and what each service is capable of presenting is provided in [Table 3](#).

It is useful to note that novel motifs can also arise from a known or previously characterised arrangement in a different structural context. One such example is where a UAU Hoogsteen, Watson-Crick base triple, which is a known arrangement, was

Table 2 Comparison of web servers for RNA 3D motifs and substructures searching. A comparison of the eleven web servers for 3D motif searching in terms of their input, algorithm and output

[illegible]

Table 3 Comparison of the various results from the different tools for a T box riboswitch (PDB ID 4MGN) used as an input query. For services that require at least two input structure, the PDB entry for another T box riboswitch (PDB ID 4LCK) was also provided

Search	Server	
Motifs/substructures/ patterns	NASSAM	Returned one annotation of an A-minor motif and four annotations of base triple.
	WebFR3D	The server was unavailable for a period of time during this comparison due to repairs and upgrades.
	R3D- BLAST	The webserver searched one chain at a time; thus needing the search to be executed twice - once for each chain Chain A: Returned 12 hits of similar structures compared to 4MGN_A. Chain B: Returned 511 hits of similar structures compared to 4MGN_B.
	RAG-3D	Similar to the R3D-BLAST option, the RAG-3D searched only one chain at a time. Therefore, the search is done in two times by using Chain A and Chain B. Chain A (glyQS T box riboswitch): Returned 10 hits of similar structures compared to 4MGN_A and 90 hits of similar substructures compared to substructures of 4MGN_A. The similar substructures resulted from the nine subgraphs of the query topology (4MGN_A) that represented the input structure. Chain B (tRNA-glycine): Resulted 10 hits of similar structures compared to 4MGN_B and no substructure reported. The 10 hits from the 4MGN_B searched are different from the search of 4MGN_A.
	COGNAC	The webserver provides options to annotate the clusters of bases that are connected by hydrogen bonds in a structure or to annotate and compare two input structures. In this case study we annotate and compare two input structures which are 4MGN and 4LCK. COGNAC returned 15 annotations of base triples, six annotations of quadruple base Type 1, an annotation of quadruple base Type 2, two annotations of quintuple base Type 1, an annotation of quintuple base Type 2 and an annotation of sextuple base Type 1 for 4MGN. Compared to 4LCK, COGNAC returned 10 annotations of base triples and two annotations of quadruple base Type1. An annotation of base triples of 4MGN and 4LCK annotated at similar location in tRNA glycine's o-arm and variable loop.
	FASTR3D	No results returned – the 4MGN structure was not in the database used and no option to upload structures is available.
Alignment of RNA tertiary structures	ARTS	The webserver is temporary unstable.
	RCLICK	The server needs two input structures to execute the alignment. 4MGN is compared to 4LCK. The results of two structures are viewed using JSMol viewer. Rclick shows the alignment of RNA interactions between both input structures. Based on the results of the output, the value of the RMSD given is 2.07 Å. The hits of match residues for 4mgn when compared to 4LCK is 105 atoms. The server also returns with structure overlap of 33.55% and highlighted the aligned residues of the input structures using JSMol viewer.
	iPARTS2	The webserver requires the structures to be searched only one chain at the time and need two structures to be executed. Thus, the global alignment search is done between 4MGN and 4LCK with different chains. Chain IDs with T box riboswitch structure: Chain C of 4MGN is superimposed with chain C of 4LCK and returned with 84 hits of aligned residue pairs. The RMSD obtained from the alignment is 4.490 Å. Chain IDs with tRNA-glycine: Chain B of 4MGN is superimposed with chain B of 4LCK and returned with 68 hits of aligned residue pairs. The RMSD value resulted with 2.961 Å.
	SARA	Provides two options of search that are structure-based function assignment and pair-wise structure alignment. The case study search is done using the structure-based function assignment because it required an input of file in PDB format to be searched throughout the SCOR database with the parameter to also search against RNA structures that are larger than 1000 nucleotides. Returned 192 structures sorted based on the mean of the negative logarithm of the three <i>P</i> -values (MEANLN). The three <i>P</i> -values are negative logarithm of the <i>P</i> -value of the sequence alignment score (LNPID), negative logarithm of the <i>P</i> -value of the secondary structure alignment score (LNPSS) and negative logarithm of the <i>P</i> -value of the structure alignment score (LNPSI). (LNPSI).
	SETTER	The webserver provides options for the structures to be aligned as a whole structure or based on the selected chain. In this case study we aligned 4MGN and 4LCK for the whole structure and based on the selected chain (chain C) for both structures. The chain C represents the T-box riboswitch. The SETTER provides the alignment quality measures, which are RMSD, the percentage of structural identity (PSI), the percentage of sequence identity (PID), the number of aligned nucleotides and the number of exact base matches. The alignment quality for 4MGN and 4LCK are 2.209 for the RMSD, 0.060 for the PSI, 0.019 for the PID, 19 nucleotides were aligned and 6 bases matches. The alignment quality for the chain C for 4MGN and 4LCK are 1.794 for the RMSD, 0.233 for the PSI, 0.070 for the PID, 20 nucleotides were aligned and 6 bases matches.

found by the computer program NASSAM to be in a stacked arrangement on top of each other at a junction holding three subdomains of domain V in the prokaryotic 23S subunit and was found to be conserved in all available 23S subunit structures at the time it was reported (Firdaus-Raih *et al.*, 2011). In this particular case, annotation of the base triples led to the discovery that there were two of the same triples stacked together – such an arrangement may not be obvious even on close visual inspection due to the dense packing of nucleotides and the difficulty in discerning 3D motifs when visualizing these structures.

We further used the COGNAC service to compare and identify atomic level differences of base arrangements connected by hydrogen bonding interactions. This was demonstrated by using the structures of two mutant cyclic dinucleotide bis-(3'-5')-cyclic dimeric guanosine monophosphate (c-di-GMP-I) riboswitch that were bound to GpA (PDB ID 3UD4) and pGpA (PDB ID 3UD3) (Smith *et al.*, 2012). Due to space limitations, we selected only the base triple interactions to illustrate the differences between the structures. In 3UD4, six base triples interactions were annotated: U53.C55.G85, C17.C93.G14, G97.C13.G94, G94.C93.G14, G94.C93.G17 and C93.G94.C13; while in 3UD3, three base triple interactions were annotated: U53.C55.G85, C17.C93.G14, G97.C13.G94 (Fig. 1). Three of the base triples interactions in 3UD3 can be found in 3UD4, however a slight shift in the base arrangement between C93 and C94 in 3UD3 resulted in the loss of the hydrogen bonds between atom N4 of C93 and atom O6 of G94 (Fig. 1).

The differences in base interactions detected occurred on the opposite end to where the ribonucleoprotein interactions were occurring and closer to the sites of where pGpA and GpA binding occurred. This can imply those interactions differences observed may be due to the differences brought about by interactions with these two different molecules. However, as always, care must be taken when interpreting such data because they can also be experimental artifacts (i.e., crystallographic packing, X-ray resolution). Nevertheless, the differences can provide clues that can assist in forming hypotheses and thus lead towards experiments that can be more conclusive.

Discussion and Future Directions

There is a tendency to concentrate on descriptions and cataloguing with little reference to the relevance interactions in a functional context when computational means are deployed to annotate RNA structures. Perhaps this is not unexpected due to the need to first develop such capacity. However, the future direction of developments in this field should take into consideration more intensive integration of the mechanistic insights that can be gained from the annotation of structural motifs, particularly for base motifs and base interactions.

As larger and more complex structures, such as the ribosomal assemblies, are solved via crystallographic and Cryo-EM approaches, there is a clear need for computational approaches that can accurately annotate these structures and provide a means of comparison between them. In the case of NMR structures, the atomic level differences between the different models can be

Fig. 1 Comparison and identification base arrangements arising from differences in the base-base hydrogen bonding interactions. The comparison and identification of the atomic level differences of base arrangements connected by hydrogen bonding interactions using the COGNAC service. This was demonstrated by using the structures of two mutant cyclic dinucleotide bis-(3'-5')-cyclic dimeric guanosine monophosphate (c-di-GMP-I) riboswitch that were bound to GpA (PDB ID 3UD4) and pGpA (PDB ID 3UD3).

quickly annotated and discerned. Such annotations can provide a useful mapping of the differences in base interactions and arrangements in the different models and correlated to biological or experimental context. Additionally, the ability to track the changes in the annotation, especially for NMR models, can be especially useful for tracking the dynamics of the RNA conformation with regard to the formation and/or deformation of base interactions and the effects these changes have on biological function.

Introduction

RNA

The Central Dogma of Molecular Biology (Crick, 1958) has long recognized messenger RNA (mRNA) as an intermediary molecule for decoding genetic information to functional molecules. Along with transfer RNA (tRNA) and ribosomal RNA (rRNA), the roles of RNA molecules were primarily linked to protein synthesis. However, the current knowledge of RNA species has extended beyond mRNA, tRNA, and rRNA. Other RNA transcripts that are not translated to proteins (non-protein coding or ncRNA) such as microRNA (miRNA), small interfering RNA (siRNA), piwi-interacting RNA (piRNA) and long non-coding RNA (lncRNA). They partake in numerous other important cellular roles that include posttranscriptional modification and gene expression regulation. RNA molecules can be self-folded to form complex three-dimensional (3D) shapes that in turn allow them to perform functions similar to proteins such as catalysis. Examples of such RNA enzymes, termed ribozymes, were discovered in the 1980s (Guerrier-Takada *et al.*, 1983; Kruger *et al.*, 1982). Such independent catalytic capacity lends support to the RNA world hypothesis (Robertson and Joyce, 2012; Cech, 2012; Gilbert, 1986).

All RNA is transcribed through the complex machinery of RNA polymerase (RNAP). Bacteria uses a single type of RNAP for all RNA transcription while eukaryotic cells generally contain RNA polymerases I, II, and III. RNA polymerase I is responsible for the synthesis of ribosomal RNA (rRNAs) 28S, 18S, and 5.8S; RNA polymerase II transcribes mRNA, snRNA, and microRNA; RNA polymerase III is responsible for transcribing tRNA, 5S rRNA, and other small RNAs.

RNA Sequence and Structure Analysis

There are three levels of RNA structure – Primary, secondary, and tertiary. The primary structure can be obtained from the DNA sequence. However, the actual RNA polynucleotide may contain posttranscriptional modifications of the sugar moieties and nucleotide bases, as well as the results of splicing such as in the case of pre-mRNA (Batey *et al.*, 1999) that are not present in the DNA sequence. A single-stranded RNA is able to form different types of secondary structure elements including stems, bulges, pseudoknots, hairpin loops, internal loops, and multiloops. These elements will then fold to form the 3D structures that are able to execute their intended biological functions. Similar to proteins, the sequence composition and resulting 3D structure of the folded RNA molecule dictate their biological functions. For example, although mRNA is generally regarded as a single-stranded sequence, its local sequence patterns are able to form secondary structures that have been shown to have important roles in regulating protein expression (Kudla *et al.*, 2009; Hall *et al.*, 1982).

Studies into the relationships of the sequences to the secondary and tertiary structure of tRNAs in the 1960s were important milestones that enabled RNA structure prediction. The tRNA molecules, which generally consist of ~76–90 nucleotides, were shown to form a conserved cloverleaf secondary structure with four helical segments that accommodate anticodon, acceptor, D, and T arms despite sharing low sequence identities (Rajbhandary *et al.*, 1967; Madison *et al.*, 1966; Holley *et al.*, 1965). These secondary structure predictions were confirmed with the determination of the three-dimensional (3D) structure of RNA for yeast alanine transfer RNA (Kim *et al.*, 1974; Robertus *et al.*, 1974; Kim *et al.*, 1973; Holley *et al.*, 1965).

The knowledge that RNA secondary structures can be evolutionarily conserved despite low sequence identity spurred the development of RNA secondary structure prediction methods. The advent of these methods led to the prediction of the secondary structures of the ribosomal RNAs - the 5S, 16S, and 23S subunits (Noller and Woese, 1981; Noller *et al.*, 1981; Woese *et al.*, 1980; Fox and Woese, 1975). The RNA secondary structure prediction algorithms were further improved by using a combination of sequence comparison analysis, thermodynamic parameters that quantified the minimum free energy of structure folds, chemical modification experiments, and pseudoknot predictions (Reuter and Mathews, 2010; Mathews *et al.*, 2004, 1999, 1997; Lück *et al.*, 1996; Zuker and Stiegler, 1981). Other parameters, including the implementation of the centroids Boltzmann-weighted ensemble model (Ding *et al.*, 2008) and maximization of the expected base-pair accuracy (Lu *et al.*, 2009), were able to further improve the secondary structure predictions. These algorithms have now been implemented as web accessible tools allowing for users to generate RNA secondary structures from sequence data – Examples of such tools are the Vienna RNA secondary structure server (see “Relevant Websites section”) (Hofacker, 2003) and RNAstructure (see “Relevant Websites section”) (Bellaousov *et al.*, 2013).

Although the predicted secondary or tertiary structures of RNA can be confidently used to provide biological function information, experimentally determined RNA structures remain crucial in providing atomic level insights on the mechanisms of specific RNA molecules. The first crystal structure of tRNA that was determined in 1970s provided the evidence that allowed for the validation of the interactions predicted in the cloverleaf secondary structure model. The tRNA molecule was folded into an L-shaped molecule with the nucleotide components stabilized via hydrogen bonding and base stacking, thus further lending

credence to the hypothesis that all tRNA may share a similar structure due to the specific position requirement of the anticodon loop and acceptor stem (Kim *et al.*, 1974; Robertus *et al.*, 1974; Kim *et al.*, 1973).

Since then, many 3D structures of RNA molecules such as the hammerhead ribozyme, group I ribozyme domain, hepatitis delta virus ribozyme, ribosomal RNAs, and small nuclear RNA (Nguyen *et al.*, 2016; Yan *et al.*, 2015; Ogle *et al.*, 2001; Ban *et al.*, 2000; Schluenzen *et al.*, 2000; Wimberly *et al.*, 2000; Ferré-D'Amaré *et al.*, 1998; Cate *et al.*, 1996; Scott *et al.*, 1995) have been determined. The availability of a wider set of experimentally determined 3D structures had also allowed for progress to be made in the development of methods for RNA fold and motif analysis (Butcher and Pyle, 2011; Klosterman *et al.*, 2002; Batey *et al.*, 1999; Ferré-D'Amaré and Doudna, 1999).

Due to the difficulty of experimentally acquiring high-resolution three-dimensional structures of RNA molecules using either nuclear magnetic resonance spectrometry (NMR), X-ray crystallography, or electron microscopy (Cryo-EM), computational methods that can predict RNA structural information and allow for their comparisons, are useful tools that can take advantage of the availability of the numerous genome sequences.

These computational approaches do share some similarity to 3D structure prediction of proteins in using approaches that include fragment assembly (including Monte-Carlo algorithms) such as for the programs FARNA, DMD, FARFAR (Das *et al.*, 2010; Ding *et al.*, 2008; Das and Baker, 2007), molecular dynamics simulations used in iFoldRNA (Sharma *et al.*, 2008); and the nucleotide cyclic motif employed by MC-Fold and MC-Sym (Parisien and Major, 2008). Many other 3D RNA structure prediction tools can be found in the “Relevant Websites section”.

The key function of the ribosome to synthesize proteins is conserved in all domains of life including organelles. Due to this, the structure of the ribosome is also generally conserved despite variations in the nucleotide sequence (Table 1). This allows for the study of how these sequences evolved while maintaining the ultimate requirement of needing to preserve the end structure that can be formed. In this article, we explore the bioinformatics tools of varying utility that can be used to compare RNA sequences and structures to provide functional and evolutionary insights.

Background

Ribosomal rRNA

More than half of the cellular RNA content is rRNAs (Russell and Zomerdijs, 2006). The rRNAs form the main structural components of the ribosome's protein synthesis machinery. Generally, two-thirds of the ribosome consists of rRNA while the remainder is made up of ribosomal proteins; however, an opposite ratio exists for mammalian mitochondrial ribosomes (Sharma *et al.*, 2003). Ribosomes are assembled from two ribosomal subunits, the small ribosomal subunit (SSU), specifically the 30S for prokaryotic cells and 40S for eukaryotic cells, and the large ribosomal subunit (LSU), specifically 50S for prokaryotic cells and 60S for eukaryotic cells. The two ribosomal subunits form the 70S and 80S ribosomes in prokaryotes and eukaryotes, respectively, while mitochondrial organelles contain 55S ribosomes. Each subunit contains a number of ribosomal proteins and rRNAs as shown in Table 1. The rRNA molecules have extensive secondary structure that together with the ribosomal proteins assemble into the large RNA–protein complex that is the ribosome.

Table 1 General components of ribosome

	Bacteria ^a	Archaea ^a	Chloroplast ^{b, c}	Eukaryote ^a	Mitochondria	
					Mammalian ^a	Fungi ^d
Ribosome		70S		80S	55S	67S–74S
Molecular weight (MDa)		2.3–2.6		3.3–4.5	~2.7	3–3.3
Small subunit						
Sedimentation coefficient	30S		30–35S	40S	28S	37S

Bioinformatics Tools in Ribosomal SSU rRNA Sequence and Structure Studies

The SSU rRNA is involved in decoding of mRNA (Carter *et al.*, 2000; Clemons *et al.*, 1999) while the large ribosomal subunit rRNA (LSU rRNA) is the site of the peptidyl transferase center (PTC) with ribozyme activity that catalyzes the formation of the peptide bond during protein synthesis (Ban *et al.*, 2000; Noller *et al.*, 1992).

SSU rRNA Sequence Studies

Sequence and phylogenetic studies of the SSU rRNAs have been intensively carried out for the past few decades (Cannone *et al.*, 2002; Gutell *et al.*, 1994; Woese, 1987; Gutell *et al.*, 1985) with the first 16S rRNA completely sequenced for *E. coli* in 1978 (Brosius *et al.*, 1978). The SSU rRNA sequence is particularly useful for phylogenetic studies because it is generally accepted that the SSU rRNA genetic material does not undergo horizontal gene transfer. Furthermore, each domain of life contains universally conserved sequences within a close phylogenetic distance while at the same time containing variable regions as a result of evolution that are significant enough to serve as molecular markers to distinguish eukarya, bacteria, and archaea or between species in the same domain of life (Woese *et al.*, 1990). There are nine commonly known conserved regions (C1–C9) and nine variable regions (V1–V9) in SSU rRNA, although the variability for some of the variable regions differ between eukaryotes and prokaryotes (Hadziavdic *et al.*, 2014; Neefs *et al.*, 1993).

Considering that structural elements may play a role in evolution, analysis of evolutionary rates across the entire rRNA has shown that structural elements in the rRNA do evolve with different rates, and this rate also varies between the different domains of life. For instance, nucleotides at the conserved regions were found mainly unpaired while sequences that form stems in bacteria or loops in eukaryotes tend to evolve faster. At the 3D structure level, the regions that are important for protein synthesis including the decoding center of SSU rRNA and the PTC of LSU rRNA were consistently more conserved than the residues on the surface of the ribosome thus suggesting that the structurally dependent functional roles of these nucleotides are the reason for their conservation (Smit *et al.*, 2007; Wuyts *et al.*, 2001; Woese *et al.*, 1980).

There are approximately 6 million SSU rRNA (16S/18S) sequences available in the high quality ribosomal RNA databases as of December 2017 in the SILVA Database (Quast *et al.*, 2012) (see “Relevant Websites section”). The availability of such a vast number of rRNA sequences has permitted faster and more accurate analysis of rRNA using sequence alignment tools. For instance, one can apply BLASTN (Basic Local Alignment Search Tool) (Altschul *et al.*, 1990) to find the species or closest homolog of a newly acquired rDNA sequence. If the analysis entails the comparison of several selected rRNA sequences from different species, multiple sequence alignment (MSA) programs such as Clustal W (Larkin *et al.*, 2007; Thompson *et al.*, 1994), T-Coffee (Tree-based Consistency Objective Function for alignment Evaluation) (Notredame *et al.*, 2000), and MAFFT (Katoh and Standley, 2013; Katoh *et al.*, 2002) can be used. A phylogenetic tree can then be constructed from the output of the MSA results. Nonetheless, these sequence alignment programs depend only on the primary sequence similarity of rRNA without considering any features of the evolutionarily conserved secondary structures.

Alignment programs that integrate covariation analysis and specifically intended for use with rRNA sequences that integrate covariation analysis have also been developed. For example, the Infernal (INFERence of RNA Alignment) program has been designed to align rRNA more accurately by applying a model-based approach using covariance models that can recognize covariations or patterns of conserved base pairs in the rRNA secondary structure (Nawrocki and Eddy, 2013; Eddy and Durbin, 1994). The concepts and methods associated with RNA comparative sequence analysis and structure prediction can also be obtained at <http://www.ma.cbb.utexas.edu/CAR/1D/> (Cannone *et al.*, 2002). To deal with the high volume of rRNA sequences from the different species available, programs such as SINA (SILVA Incremental Aligner) (Pruesse *et al.*, 2012) have been developed.

The available SSU rRNA sequences are an important resource for studying evolution that are housed in several high quality updated SSU rRNA databases that include SILVA (Quast *et al.*, 2012), RDP (Cole *et al.*, 2013), Greengenes (McDonald *et al.*, 2012), and National Center for Biotechnology Information (NCBI) (Federhen, 2011). To ease the phylogenetic study of SSU rRNA sequences, including those that are newly sequenced from previously unstudied organisms, one can apply comprehensive software packages like SSU-ALIGN (Nawrocki, 2009) that contain tools to identify, analyze, perform secondary structure alignment, and visualize SSU rRNA. A rRNA sequence identified from a newly sequenced genome also can be annotated using programs such as RNAmmer (Lagesen *et al.*, 2007) and HMMER 3.0 (Huang *et al.*, 2009) or web-based tools such as EzCloud (see “Relevant Websites section”) (Yoon *et al.*, 2017).

SSU rRNA Secondary Structure Predictions

Pairwise and MSAs of SSU rRNA are not able to provide a structural level insight for the sequences being compared. However, secondary structure prediction is crucial for providing a higher level of understanding with regard to evolutionary and functional conservation of SSU rRNA. Unlike RNA folding algorithms that predict secondary and tertiary structures based on their global minimum energy or by using free energy minimization that involves thermodynamic parameters (Mathews *et al.*, 1999; Zuker, 1989; Zuker and Stiegler, 1981), comparative analysis of rRNA secondary structures is based on the principle that RNA with different sequences are able to form similar structures (secondary and tertiary) and the unique structures with functional features will be evolutionarily conserved (Gutell *et al.*, 2002; Woese *et al.*, 1983, 1980; Noller *et al.*, 1981). The free energy minimization

approach was reported to be less accurate for generally long RNA secondary structure prediction including SSU rRNA (Doshi *et al.*, 2004). The accuracy of covariation based rRNA comparative analysis was further improved with the availability of a high number of rRNA sequences (Gutell *et al.*, 2002, 1986; Gutell, 1996).

In the 1980s, the secondary structures of 16S rRNA were predicted and described using comparative sequence analysis and combined to data of chemical modifications and enzymatic assays (Gutell *et al.*, 1985; Woese *et al.*, 1983, 1980). In general, a prokaryote 16S secondary structure that consists of about 1550 nucleotides can be arranged into several domains – including 5' domain, central domain, 3' major domain, and 3' minor domain – which assemble into 50 helices for SSU rRNA. Comparisons of SSU rRNA secondary structures for prokaryotes, eukaryotes, and organelles have revealed core structural features that are conserved in all SSU rRNA, and in addition, unique structural features for each domain of life or organelles were also identified. For example, 18S rRNA is more complex with less regular helices and bigger loops compared to bacterial 16S rRNA (Woese *et al.*, 1983). Integrating sequence alignments to secondary and tertiary structure analysis of SSU RNAs further revealed unique features of SSU rRNA conserved and variable regions that can be applied to distinguish a species at the molecular level and for categorization as eukarya, bacteria, or archaea (Woese *et al.*, 1990; Woese, 1987).

For instance, all bacterial SSU rRNAs were found to have a side bulge with six nucleotides at the hairpin loop (between nucleotide 500 and 545, *E. coli* numbering) that protrudes from the stalk of the rRNA structure. However, this same side bulge in archaea and eukarya were formed with seven nucleotides. Several of these distinct features were further identified to distinguish the rRNA of compared organisms, which can help in building a universal phylogenetic tree (Woese *et al.*, 1990, 1983; Gutell *et al.*, 1985). Furthermore, analysis of SSU rRNAs from organelles such as the 16S rRNA of chloroplast and the 12S rRNA of mitochondria also revealed substantial similarities of the primary sequences and at secondary structure level despite being of very different lengths thus suggesting that the core sequence and structure of rRNA is also conserved in the ribosomes of organelles (Zwieb *et al.*, 1981). In knowing that the secondary structures of SSU rRNA are more conserved than the sequence, differences in the secondary structures between SSU rRNAs have been extracted for taxonomic and evolutionary studies (Du *et al.*, 2017). Comparison of all SSU rRNA secondary structures when mapped across the three domains of life obtained from Comparative RNA Web (CRW) (Mears *et al.*, 2002) provides a valuable picture of phylogenetic conservation by allowing for the identification of nucleotides or structural regions that are either highly conserved or variable.

Secondary structure studies of SSU rRNAs before the atomic structure of the ribosome were determined to have contributed to the early functional understanding of the ribosome. For example, the highly conserved sequence and secondary structure of 530 loop region of the 16S rRNA, which consists of nucleotide G530, was predicted to form a pseudoknot that was of structural and functional importance in protein translation (Powers and Noller, 1991). When the atomic resolution structure of the 30S ribosome was solved, it was indeed revealed that the 530 loop is interacting with the anticodon stem-loop of tRNA that recognizes the mRNA codon at the ribosomal A site. The nucleotide G530 in the 530 loop together with bases A1492 and A1493 on helix 44 of SSU rRNA are now known to be crucial for correct codon–anticodon interaction during the decoding process (Ogle *et al.*, 2001).

Computer programs such as SSU-DRAW, which is part of the SSU-ALIGN package (Nawrocki, 2009), can generate secondary structures of newly identified SSU rRNAs with a high degree of confidence by using a template-based comparative analysis method. However, comparative analysis with covariation approach is still not able to reveal noncanonical base pairings that are often found in complex RNA structures such as rRNA. More recently available structure prediction approaches can integrate information on specific geometric and molecular interactions obtained from experimentally determined rRNA 3D structures that may thus improve secondary structure prediction (Petrov *et al.*, 2014).

SSU rRNA 3D Structure Studies

While sequences of SSU rRNA are now fairly easy to obtain via DNA sequencing and from there the secondary structure can also be predicted with high confidence, the accurate computational prediction of its 3D structure is still not possible. This is due to the generally long sequences that are in excess of 1000 nucleotides that also have interactions with ribosomal proteins in order to form the mega Dalton RNA–protein complex. Nonetheless, much effort is ongoing towards developing accurate tools for RNA 3D structure prediction. One initiative in this direction is RNA-Puzzles, a collective blind experiment to evaluate RNA prediction techniques (Cruz *et al.*, 2012).

At present, the 3D structure of SSU rRNA can only be acquired by determining the structure of the ribosome. X-ray crystallography and cryoelectron microscopy (cryo-EM) remain the only routes to experimentally obtain the ribosome's structure. The 3D coordinates of the rRNA chains can be extracted from the atomic resolution structures of the ribosome that have been deposited in the Protein Data Bank (PDB). Ribosomal RNA forms a stable ribosomal subunit when in complex with ribosomal proteins; this may explain why no independent structures of rRNA are available.

The 3D structure of rRNA can be analyzed and displayed with available molecular visualization software already being used for protein structures such as COOT (Emsley and Cowtan, 2004), Chimera (Pettersen *et al.*, 2004), PyMOL (Delano, 2002), and several others. Other programs such as Ribovision (Bernier *et al.*, 2014) were exclusively designed to visualize and analyze the primary sequences as well as secondary and three-dimensional structures of rRNA in a single platform. Selected bioinformatics tools that are available for sequence and structure analysis of SSU rRNA are listed in Table 2.

In 2000–2001, the high-resolution crystal structures were obtained for the 30S ribosomal subunits from thermophilic bacteria, *Thermus thermophilus* (Ogle *et al.*, 2001; Wimberly *et al.*, 2000; Schlueder *et al.*, 2000) and the 50S subunit from the halophilic

archaeon, *Haloarcula marismortui* (Ban *et al.*, 2000), which revealed in great depth the details of how the ribosome decodes mRNA and synthesizes the corresponding polypeptide en route to becoming a functional protein molecule. For the first time, the previously predicted secondary and tertiary structure of rRNAs could be compared and validated against experimentally determined examples. As a testament to the accuracy of the prediction tools, about 97%–98% of previously predicted rRNAs' base pairings were indeed found in the ribosomal crystal structures (Gutell *et al.*, 2002).

Advancements in cryo-EM and X-ray crystallography have resulted in several high-resolution ribosomal structures being determined for the ribosomes of eukaryotic species – human, protozoa, and yeast – (Zhang *et al.*, 2016; Khatter *et al.*, 2015; Wong *et al.*, 2014; Ben-Shem *et al.*, 2011; Rabl *et al.*, 2011) as well as the ribosome of organelles – mitochondria (human, pig, and yeast) and chloroplast (spinach) (Desai *et al.*, 2017; Amunts *et al.*, 2015; Greber *et al.*, 2015). Comparisons of SSU rRNA crystal structures for bacteria and eukaryotes have revealed that both domains of life share a similar structure at several of the hypervariable regions and help to provide information on secondary structure mappings that were not previously identified in 18S rRNA (Lee and Gutell, 2012).

Case Studies: Sequence Alignment Guided Structure Analysis of SSU rRNA From Prokaryotes, Eukaryotes, and Organelles

High-Resolution Ribosome Structures

Fourteen high-resolution ($<4\text{\AA}$) structures of whole ribosomes available in the PDB were selected for this case study to demonstrate MSA guided structure analysis of SSU rRNA for two domains of life (prokaryote and eukaryote) and organelles (chloroplast and mitochondrial). The domain archaea was not included due to the lack of atomic structures for their 70S and 30S ribosomes. The selected target ribosomes include **prokaryotic 70S ribosomes**: Gram-negative bacteria *Escherichia coli* (PDB ID: 4YBB), and *Thermus thermophilus* (PDB ID: 4V51), Gram-positive bacteria *Bacillus subtilis* (PDB ID: 3J9W) and *Staphylococcus aureus* (PDB ID: 5LI0); and *Mycobacterium tuberculosis* (PDB ID: 5V93) and *Mycobacterium smegmatis* (PDB ID: 5O61); **Eukaryotic 80S ribosomes**: *Saccharomyces cerevisiae* (PDB ID: 4V88), *Homo sapiens* (human) (PDB ID: 4UG0), *Leishmania donovani* (PDB ID: 5T2A) and *Plasmodium falciparum* (PDB ID: 3J7A); **Mitochondrial ribosomes**: *Saccharomyces cerevisiae* mitoribosome (PDB ID:

5MRC), *Sus scrofa* (Porcine) mitoribosome (PDB ID: 5AJ3) and *Homo sapiens* 55S mitoribosome (PDB ID: 3J9M); **Chloroplastid 70S ribosome:** *Spinacia oleracea* (spinach) chloroplast ribosome (PDB ID: 5MMM).

Multiple Sequence Alignment and Phylogenetic Tree Construction

The SSU rRNA sequences corresponding to the species of selected ribosomes including the SSU rRNA of *E. coli* (16S_E_coli), *T. thermophilus* (16S_T_thermophilus), *B. Subtilis* (16S_B_subtilis), *S. aureus* (16S_S_aureus), *M. smegmatis* (16S_M_smegmatis), *M. tuberculosis* (16S_M_tuberculosis), chloroplast of *S. oleracea* (16S_S_oleracea_Chloroplast), *S. cerevisiae* (18S_S_cerevisiae), *L. donovani*

Fig. 1 Multiple sequence alignments for the SSU rRNA of 14 selected species with high-resolution ($< 4 \text{ \AA}$) ribosomal structures that were analyzed using fast Fourier transform and with the results subjected to phylogenetic tree construction using the neighbor-joining method with MAFFT (<https://mafft.cbrc.jp/alignment/software/>). (A) The MSA result in Clustal format as visualized using Esprout program with the highly conserved regions highlighted in red (A). (B) The phylogenetic tree as visualized using Phylo.io. The variable regions (V1–V9) of *Escherichia coli* 16S SSU rRNA are indicated with horizontal black bars. The highlighted variable region of V2 (nucleotides 144–178) indicate the nucleotides that form helix h8 in bacterial 16S SSU rRNA, but form h3 and h4 of 12S mammalian mito-SSU rRNA.

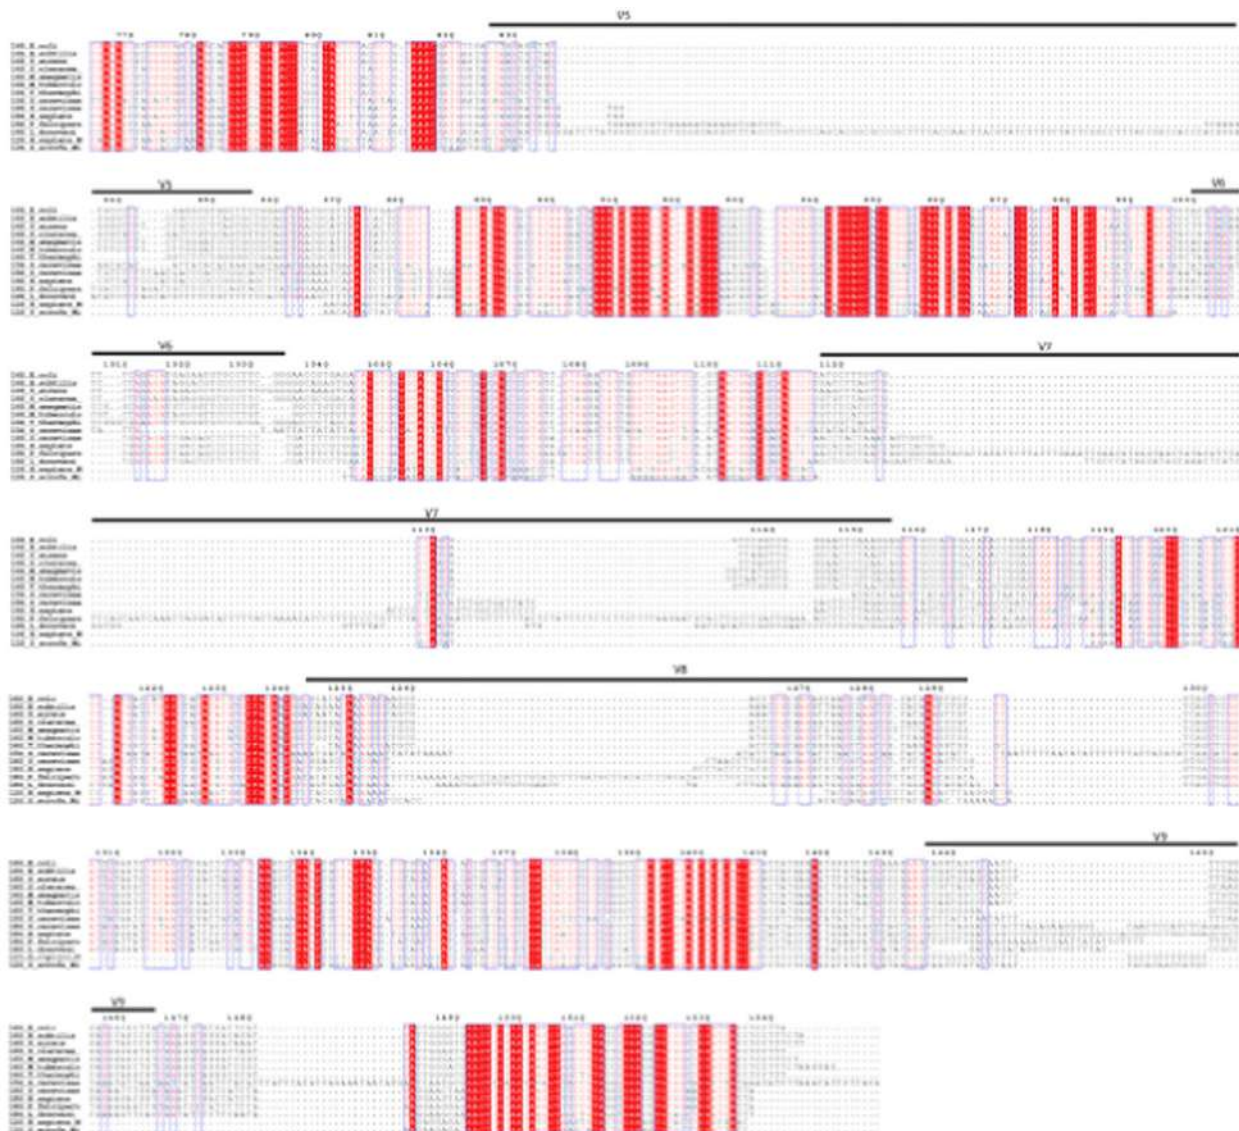

Fig. 1 Continued

(18S_L_donovani), *P. falciparum* (18S_P_falciparum), *H. sapiens* (18S_H_sapiens), mitochondrial ribosome of *S. cerevisiae* (15S_S_cerevisiae_Mitoribosome) and mitochondrial ribosome of *H. sapiens* (12S_H_sapiens_Mitoribosome) were obtained from NCBI. The FASTA formatted sequences were subjected to MSA using MAFFT, which employs fast Fourier transform in sequence alignments with an Auto setting, and then subjected to phylogenetic analysis using the neighbor-joining method (see “Relevant Websites section”). The phylogenetic trees were visualized with Phylo.io (Robinson *et al.*, 2016; Katoh and Standley, 2013; Katoh *et al.*, 2002). The MSA results in Clustal format were visualized with the ESPrnt program (Gouet *et al.*, 1999) to highlight the conserved regions.

Secondary Structure Diagram of 16S SSU RNA

The secondary structure diagrams of SSU rRNAs of human 18S, *E. coli* 16S, human mito ribosome 12S, and *S. cerevisiae* mito ribosome 15S were obtained from the Comparative RNA Web server (see “Relevant Websites section”). Additionally, an overview of SSU rRNA conserved secondary structures across the three domains of life was also obtained from CRW (see “Relevant Websites section”) (Mears *et al.*, 2002).

Comparison of 3D Structure of SSU rRNAs

The selected SSU rRNAs structure coordinates were obtained from the structures deposited in the PDB as listed in Section “SSU rRNA Sequence Studies.” The 16S rRNA of *E. coli* (PDB ID: 4YBB) was used as a reference structure for 3D structure comparisons of human 18S rRNA (PDB ID: 4UG0), 15S rRNA of *S. cerevisiae* mito ribosome (PDB ID: 4V88), and 12S rRNA of

Fig. 1 Continued

human mito ribosome (PDB ID: 3J9M). The structure superposition was carried out using least-squares fitting in the COOT program (Emsley and Cowtan, 2004). The program PyMOL (DeLano, 2002) was used to visualize all the 3D structures that were analyzed in this case study.

Results and Discussion

The sequences of the 14 selected SSU rRNAs from prokaryote, eukaryote, and organelles with nucleotides lengths of 962–2205 were aligned. Despite the significant difference in length, the MSA showed that all the SSU rRNAs were generally well aligned, particularly at the previously identified conserved regions (Baker *et al.*, 2003; Van de Peer *et al.*, 1996) including helices h18, h27, h28, h30, h31, h44, and h45. In comparison to the mammalian cell's 12S mito ribosome, all the aligned 16S and 18S SSU rRNAs were found to have insertions mainly at the variable regions V1–V9 (Fig. 1(A)). Phylogenetic analysis based on the MSA results showed that bacteria, eukaryote, and mito ribosome SSU rRNAs were shown as different branches in the unrooted tree (Fig. 1(B)). The 16S rRNA of Gram-positive, Gram-negative bacteria, and mycobacterium are closely related to each other in one branch (Fig. 1(B)). In addition, chloroplast rRNA from spinach also clustered to prokaryote SSU rRNA despite having evolved to be an organelle that is important for photosynthetic plants and algae. The eukaryotic SSU rRNA for mammals, parasites, and yeasts was also shown to be more closely related to each other. Nonetheless, unlike the nuclear ribosome, the SSU rRNA of the mitochondrial ribosome in yeast is significantly deviated compared to the mammalian mito ribosome. The overall MSA and phylogenetic analysis can clearly distinguish sequences of SSU rRNA to the domain of life and organelle that it belongs to.

While the alignments are able to show that the nucleotide sequences are universally conserved across the SSU rRNA, especially at the conserved regions, such as the helices of h1 and h2 (nucleotide 11–23) and loop 530 region of helix h18 (nucleotide 515–536, all the nucleotide numberings used refer to those in *E. coli* SSU rRNA), there are limitations for the MSA results when it comes to demonstrating the conservation for the secondary structure. For example, the nucleotides 144–178 (V2 region) are known to form helix h8 in 16S rRNA, however similar residues of the mito ribosome were found to form helices h3 and h4 of 12S rRNA (Fig. 1(A) and Fig. 2(A)). The use of sequence comparisons alone is unable to provide a structural context to the RNA molecule. Comparisons of secondary structure are therefore necessary to further identify conservation in the RNA molecules from a structural perspective.

Based on the predicted secondary structures of the 12S, 15S, 16S, and 18S SSU rRNAs that were obtained from the Comparative RNA Web server (CRW) (see "Relevant Websites section") (Cannone *et al.*, 2002) as shown in Fig. 2, all SSU rRNA secondary structure diagrams showed an overall similarity in containing the 3' minor and major domains, 5' major domains, and central domains (Fig. 2). The secondary structure regions that are formed with universally conserved nucleotides identified in the MSA (Fig. 1(A) and Fig. 2(A)) were found to be mostly conserved. Nonetheless, one can clearly identify the structural differences between

Fig. 2 The secondary structure of SSU rRNA. (A) The secondary structure of *Escherichia coli* 16S SSU rRNA with phylogenetic conservation superimposed across the three domains of life. This diagram was obtained from Comparative RNA Web (CRW) (http://www.rna.icmb.utexas.edu/SIM/4A/Minimal_Ribosome/) with slight modifications. Conserved nucleotide sequences are shown as ACGU: 98 + % conserve, acgu: 90%–98% conserved, •: 80%–90% conserved, and •: less than 80% conserved. Arcs represent the variable regions with the nucleotide number (lower and upper) known to exist. The nucleotides that were 100% conserved in the MSA shown in Fig. 1 are highlighted in purple. The helices that are conserved in the three domains of life were labeled in green, while the helices in the variable regions are in blue. Helix h8 is highlighted in yellow. (B) The secondary structures of *Escherichia coli* 16S SSU rRNA, human 18S SSU rRNA, 15S yeast mito-SSU rRNA, and 12S human mito-SSU rRNA were obtained from CRW (http://www.rna.icmb.utexas.edu/SIM/4A/Minimal_Ribosome/) for comparison. Helices h3 and h4 of 12S human mito-SSU rRNA are highlighted in yellow.

the compared SSU rRNAs. For example, while the head region is highly similar, the bottom region was significantly deviated (Fig. 2(B)). Such structural deviations will provide a better understanding of the evolutionary events that specific regions of the RNA molecule had undergone. Although the secondary structure is informative in revealing the general structure conservation of the RNA molecule that is missing in sequence alignments, it remains difficult to predict noncanonical base pairings and highly idiosyncratic RNA sequences – For example, a GC pairing can be assumed to conform to the Watson–Crick geometry but in reality, that GC pairing may actually be of the noncanonical reverse Watson–Crick arrangement. Recently, high-resolution structures have been used to aid in constructing a more complete and accurate secondary structure map of SSU rRNA (Petrov *et al.*, 2014).

The overall shape of SSU rRNAs in this case study, with the head, neck, beak, platform, body, shoulder, and spur features can be clearly discerned using molecular visualization (Fig. 3). The 12S mammalian mt-SSU rRNA was shown to have a contracted form in accordance to its shortest sequence length, while 15S, 16S, and 18S SSU rRNA have similar overall dimension (Fig. 3(A)). The contracted mammalian mt-SSU rRNA has been known to recruit more proteins in order to perform the specific synthesis of hydrophobic integral membrane proteins (Amunts *et al.*, 2015; O'Brien, 2003). The yeast 15S mt-SSU rRNA had not undergone similar evolutionary events compared to its mammalian counterpart and thus maintains a size similar to bacterial 16S rRNA. The expansion segments of 18S human SSU rRNA compared to 16S SSU rRNA can also be identified (Fig. 3(B)). For detailed in depth discussion of the features for each SSU rRNA structure, please refer to the respective original publications. Overall, the 3D structures provide details that reveal universally conserved regions as well as structural features that show how rRNA have evolved specifically for a particular domain of life and organelles.

Fig. 3 The 3D structure of SSU rRNAs. (A) The 3D structure of SSU rRNAs were shown in same dimension by superimposed to the loop 530 nucleotides (cyan) of *Escherichia coli* 16S SSU rRNA. The nucleotides found to be 100% conserved in multiple sequence alignment of Fig. 1(A) are shown as pink in *E. coli* 16S SSU rRNA. The figure is generated by using the program PyMOL. (B) Comparison of SSU rRNA by superimposing of 12S human mito-SSU rRNA, 15S yeast mito-SSU rRNA, and 18S human SSU rRNA (gray) to 16S *E. coli* SSU rRNA (orange). ES indicates part of the expansion segments of 18S human SSU rRNA.

Fig. 4 The induced-fit conformational change that was employed for the universally conserved nucleotides upon cognate tRNA binding demonstrated that the RNA molecule is dynamic in carrying out its biological function. Both A1492 and A1493 were shown to flip out from helix 44 for *Thermus thermophilus* 16S subunit (pink). The same nucleotides in the yeast mito-SSU rRNA (gray) remained in the helix.

In **Fig. 4**, nucleotides A1492 and A1493 are shown to flip out from helix 44 of *T. thermophilus* 16S (PDB ID: 4V51), while the same nucleotides for the yeast mito-SSU rRNA remained in the helix. These nucleotides are known to be universally conserved and important for cognate tRNA recognition at the A site (Selmer *et al.*, 2006; Ogle *et al.*, 2001; Wimberly *et al.*, 2000). Here, the nucleotides in *T. thermophilus* 16S were shown at the stage of where the ribosome is bound with cognate tRNA at the A-site of 16S SSU rRNA, while 15S mito-SSU rRNA of yeast is in the empty form (without cognate tRNA at the A-site). Despite the universally conserved sequences, as well as overall agreement of the secondary and overall tertiary structures for loop 530 and helix 44, the use of an induced-fit conformational change on the localized nucleotides upon the cognate tRNA binding (Ogle *et al.*, 2001) demonstrating that the RNA molecule is dynamic in anticipating its biological functions, hence the need to increase the complexity of the challenge to computationally predict accurate tertiary structures.

Future Directions and Closing Remarks

Currently available computational tools can be traced back to work that was first reported in the 1960s. Over the years, these programs have expanded their utility and accuracy. They are now well established in their capacity to identify well-conserved nucleotides, even in long RNA sequences with large amounts of variation. The limitation of primary structure analysis in being unable to identify structurally conserved regions with more diverse sequence variations can be complemented by secondary structure prediction methods that integrate covariation and free energy minimization approaches.

Despite improvements in secondary structure prediction methods, they are still not able to definitively discern the specific molecular arrangements for base pairings and are thus not able to differentiate canonical versus noncanonical pairs. Nevertheless, such tools remain highly functional and can provide a useful map and guidance when navigating the sequences or structures of newly acquired data for long and complex RNA molecules such as the ribosomal subunits.

RNA 3D structure prediction remains a challenge and is generally limited to chains with less than 500 nucleotides. Accurate 3D structure prediction of RNA that can correctly differentiate canonical and noncanonical pairs, as well as identify interaction sites to metal ions, organic molecules, and other macromolecules will have great utility in using the vast amount of sequence data available. Such programs can in the future trace minor evolutionary changes that are relevant from not only a sequence perspective but also with relevant structural context. They can also perhaps be applicable for the identification of RNA molecules as targets for drug development work. Initial computational screening of such targets can direct investigators towards specific RNA structures that need to be acquired for in depth experimental structural analysis.

Computational Design and Experimental Implementation of Synthetic Riboswitches and Riboregulators

Munyati Othman and Siuk M Ng, Universiti Kebangsaan Malaysia, Bangi, Selangor, Malaysia
Mohd Firdaus-Raih, Universiti Kebangsaan Malaysia, Bangi, Malaysia

Introduction

Riboregulators consist of two basic components; an aptamer domain and an actuator (effector) domain. The aptamer domains are short single stranded DNA or RNA molecules made up of 20–100 nucleotides. These oligonucleotides adopt a variety of unique 3-dimensional (3D) structures that enable binding to specific ligands with high selectivity and specificity (Dunn *et al.*, 2017). The actuator domains are located downstream to the aptamer domain will undergo a conformational change upon ligand binding and is the effector that controls regulation of gene expression (Chang *et al.*, 2012). The modularity of the actuator domain allows it to effect control of gene expression through a variety of mechanisms including transcription, splicing, stability, RNA interference, and translation (Chang *et al.*, 2012; Liang *et al.*, 2011). The mixing and matching of RNA aptamers and actuator domains leads towards a functional synthetic riboregulator construct. Due to the sequence diversity and their high affinity for specific targets, aptamers are often used in riboregulator design.

Several strategies have been used to generate aptamers as candidates for riboregulators. One obvious strategy is to select from naturally occurring aptamers that are found in riboswitches. Naturally occurring aptamers such as the thiamine pyrophosphate (TPP) aptamer domain, have previously been reengineered to control the expression of green fluorescent protein (GFP) (Nomura and Yokobayashi, 2007). Aptamers can also be designed via computational approaches; for example, an aptamer that is able to interact with cytochrome P450 had been designed using molecular modelling methods (Shcherbinin *et al.*, 2015). Additionally, aptamers can also be derived from *de novo* selection of RNA binding elements via SELEX (Systematic Evolution of Ligands by Exponential enrichment), a method that has been used to identify synthetic aptamers that exhibit high affinity to specific ligands of interest (Tuerk and Gold, 1990). The first experiment deploying this method was for the detection of RNAs that are able to interact with T4 DNA polymerase (Tuerk and Gold, 1990). Since then, the targets for these SELEX sourced aptamers have greatly expanded to encompass a variety of molecules ranging from inorganic molecules to small organic molecules that include complex structures (Stoltenburg *et al.*, 2007), amino acids (Lozupone *et al.*, 2003), metal ions (Kawakami *et al.*, 2000), small organic compounds (Mann *et al.*, 2005), biological factors (Lauhon and Szostak, 1995), metabolites (Long *et al.*, 2016), proteins (Hassan *et al.*, 2017) and antibiotic (Berens *et al.*, 2001; Wallace and Schroeder, 1998).

A SELEX process starts with chemically synthesizing random oligonucleotide libraries consisting of 10^{13} to 10^{15} different sequence motifs that are then incubated directly with the target. The oligo-target complexes formed are subsequently partitioned from unbound and weakly bound oligonucleotides. The oligo-target complexes are eluted and amplified by PCR for DNA SELEX or subject to reverse transcription (RT)-PCR for RNA SELEX. The resulting bound oligo needs to be transformed into a new oligonucleotide pool. The new and enriched pool of selected oligonucleotides is used for the binding reaction with the target in the next SELEX round. Through iterative cycles of selection and amplification, the initial random oligonucleotide pool is reduced to relatively few sequence motifs with the highest affinity and specificity for the target.

High throughput sequencing (HTS) has revolutionized the SELEX technique (Nguyen Quang *et al.*, 2016) because after a series (> 15) of selection cycles, millions of aptamer sequences can be determined from HTS datasets. Programs such as Aptamotif, MPBind, AptaCluster, APTANI and AptaPLEX were developed to analyse the fast emerging data (Hoinka *et al.*, 2012, 2014; Jiang *et al.*, 2014; Caroli *et al.*, 2016; Hoinka and Przytycka, 2016). In this paper, the tools used to analyse SELEX data and for predicting the secondary structures of riboregulators are discussed.

Background

Riboregulator

RNAs are known to mediate gene expression in both prokaryotes and eukaryotes. In prokaryotes, riboregulators such as riboswitches and ribozymes control gene expression via *cis* or *trans* interactions with their targets (Winkler *et al.*, 2004; Mandal *et al.*, 2003). In eukaryotes, small RNAs act as microRNAs in order to control gene expression (Gottesman, 2002). The regulatory capacity of such RNAs have led to *in-vitro* and *in-silico* riboregulator design that impact transcription and translation in response to specific input.

Early studies of riboregulators were conducted by Isaac and co-workers (Isaacs *et al.*, 2004). The first type of engineered riboregulator consisted of complementary *cis* RNA sequence located upstream of the ribosome binding site (RBS) in a target gene. Upon transcription, the RNA transcript forms a stem-loop that interferes with ribosome binding. However, the subsequent binding of a cognate *trans*-acting RNA acts to promote and allow translation.

Another type of riboregulator, the toehold switch, is based on RNA-RNA interactions between the switch and the trigger RNAs (Green *et al.*, 2014). The switch RNA, also known as the transducer strand, contains the initial binding site for the trigger or *trans*-acting RNA strand, ribosome binding site (RBS), start codon, a 21nts linker sequence, followed by the coding sequence of the gene. The upstream of the coding sequence forms a hairpin that blocks translation. The complementary trigger RNA strand that binds to the initial binding site will expose the RBS and the start codon in order to initiate translation of the target gene (Green *et al.*, 2014).

Both riboregulators were rationally designed and comprised of a combination of aptamer and actuator domains. At present, secondary structure prediction is commonly used to assess the quality of the riboregulators (Wachsmuth *et al.*, 2013; Topp *et al.*, 2010).

Synthetic Riboswitches

Riboswitches have become an important tool in synthetic biology due to their ability to regulate gene expression and to integrate into a more complex genetic circuit (Topp and Gallivan, 2010). Synthetic riboswitches are widely used as riboregulators; for example, those that detect theophylline and antibiotics such as tetracycline and streptomycin, have been used to activate transcription, termination and protein translation by designing different actuator domains (Wachsmuth *et al.*, 2015; Desai and Gallivan, 2004; Domin *et al.*, 2017).

Systems and/or Applications

Computer programs can be used to filter SELEX or HT-SELEX data to discover new aptamers. The assembly of aptamer and actuator domains can then be analyzed using available webserver programs.

Input Formats

Most software accept FASTQ and FASTA formatted files as input. Secondary structure prediction via RNAfold, RNAstructure and Mfold accept a single RNA or DNA sequence in plain text or FASTA format as input.

Output and Average Time for Computations

Seven aptamer analysis software are discussed in this chapter. On average, these programs take up to several hours to run, depending on the size of the input data and the technical specifications of the computer being used. For secondary structure prediction, most tools take from only a few seconds to a few minutes to provide the predicted minimal free energy (MFE) secondary structure.

Analysis and Assessment

Aptamer Analysis

Seven programs were chosen to analyse aptamer sequences from available SELEX/HT-SELEX data. The programs selected were written in Python, Perl and C + +. The general approach taken by all tools is summarized in Table 1.

Aptamotif, APTANI and AptATRACE deploy principal sequence-structure analysis to filter for aptamers (Hoinka *et al.*, 2012; Caroli *et al.*, 2016; Dao *et al.*, 2016). APTANI builds on the Aptamotif algorithm and extends its usage to analyse both SELEX and

Table 1 List of tools for the analysis of SELEX/HT-SELEX. A list of aptamer analysis programs available and the approach used by each program in analyzing aptamers

Name (Language)	Input	Search approach	Reference
Aptamotif (Python)	FASTQ	Identify sequence-structure motifs	Hoinka <i>et al.</i> (2012)
MPBind (Python/R)	FASTA/FASTQ	Predict the binding potential combination of binding of all <i>n</i> -mers within a sequence	Jiang <i>et al.</i> (2014)
AptaCluster (C + +)	FASTA/FASTQ	Cluster aptamers sequence based on k-mer counting	Hoinka <i>et al.</i> (2014)
FASTAptamer (Perl)	FASTQ	Compare population for sequence distribution, generates sequence cluster, calculator fold enrichment value and search for multiple sequence motifs	Alam <i>et al.</i> (2015)
APTANI (Python 3.3)	FASTQ	Identify aptamer motif from HT-SELEX and secondary structure information	Caroli <i>et al.</i> (2016)
AptaPLEX (C + +)	FASTQ	Standalone demultiplexing software for HT-SELEX	Hoinka and Przytycka (2016)
AptaTRACE (C + +, Java)	FASTQ	Identifying sequence structure motifs that show a signature of selection	Dao <i>et al.</i> (2016)

HT-SELEX data. Both tools use RNAsubopt to predict secondary structures in a specific energy range (Wuchty *et al.*, 1999; Backofen and Will, 2004). AptaTRACE requires Sfold or CapR for secondary structure prediction. The Sfold program needs to be installed, while CapR has been integrated into the program (Ding *et al.*, 2004; Fukunaga *et al.*, 2014). The AptaTrace process is divided into three parts: data processing, secondary structure profiling and motif extraction. The data processing involves selecting sequences as input based on user defined frequency thresholds. Then, AptaTRACER will select sequence motif(s) with the tendency of residing in a hairpin, bulge loop, inner loop, multiple loop, dangling end or being paired convergently into a specific structural context. The distribution of the k-mer's secondary structure contacts (K-context distribution) was estimated using the relative entropy (KL-divergence). In Aptamotif and APTANI, four different types of secondary structure motifs are inspected, i.e. hairpin loop left, hairpin loop right, bulge loop and intra-strand loop. The AptaTRACE program identifies hairpins, bulge loops, inner loops, multibranch loops and dangling ends.

In contrast, MPBind predicts aptamers based on a statistical test (Jiang *et al.*, 2014). The aptamer sequences are assumed to consist of combination of n -mer. The combination of n -mer is given a score based on relative frequency change and relative abundance in the database. Then the potential binding aptamer is inferred from the combination of all n -mer within the sequence.

FASTAptamer is a multi-instruction tool starts by determining sequence frequency, multiplicity or copy number via FASTAptamer-Count. The output of the analysis can then be applied as input into downstream FASTAptamer scripts such as FASTAptamer-compared, FASTAptamer-cluster, FASTAptamer-enrich, FASTAptamer-search, other FASTAptamer scripts or any program that accepts FASTAQ formatted files as input (Fig. 1). Using available scripts, the inputs are compared to the population for each sequence distribution, clusters are then generated for the sequences, the fold-enrichment of the sequences throughout the course of a selection are calculated and then the search for degenerate sequence motifs in the SELEX/HT-SELEX data is carried out (Alam *et al.*, 2015).

AptaCluster clusters SELEX/HT-SELEX data based on a calculated k-mer similarity measure (Hoinka *et al.*, 2014) that is executed in three steps. First, the data is compressed and filtered using Locality Sensitive Hashing (LSH). After filtration, the sequences with the same hash values will be in the same pool (Andoni *et al.*, 2013). Next, the clusters are extracted based on the high frequency of the sequence in the pool. Then the k-mer based on distance function is used to compute the distance between sequences and cluster them.

AptaPLEX is a standalone and independent demultiplexer specifically designed for HT-SELEX (Hoinka and Przytycka, 2016). The program can be used to analyse single or multiple HT-SELEX experiments at once. Aptaplex automatically recognizes and handles gzip compressed data and makes use of all available processing resources via its multi-threaded design while minimizing memory usage.

Secondary Structure Prediction

The stability and biochemical properties of a RNA molecule is largely determined by the base pairing interactions. After the aptamer couples with the actuator domain, secondary structure prediction is carried out. This step is important to visualise the folding of the aptamer domain, the interaction between the aptamer domain and actuator domain, or to determine the stability of the folding via its minimum free energy. Several webservers are available for secondary structure prediction - RNAstructure, RNAfold and Mfold are three of the software discussed here (Reuter and Mathews, 2010; Gruber *et al.*, 2008; Zuker, 2003).

RNAstructure uses thermodynamics and utilizes parameters from the Turner group to predict secondary structure (Reuter and Mathews, 2010). This webserver can also predict base pair probabilities using a partition function, in addition to bimolecular secondary structure and common secondary structure prediction for two or more sequences. The bimolecular secondary structure prediction folds two sequences into their lowest hybrid free energy conformation. The server combines the capabilities of bimolecular folding and duplex folding to create two distinct sets of possible bimolecular structures. To predict the common secondary structure for two or more sequences, the server combines the capabilities of Multilign and TurboFold to create distinct sets of possible structures for multiple sequences.

RNAfold is a secondary structure prediction program that is built based on algorithms proposed by Zuker and Stiegler, and John McCaskill (Gruber *et al.*, 2008). Zuker and Stiegler proposed a dynamic programming algorithm to predict the minimum free energy (MFE) of a sequence, while John McCaskill calculated the equilibrium base pairing probability of secondary structures

Fig. 1 Flow chart of FASTAptamer tools. FASTAptamer consist of multiple tools to analyse data from SELEX or HT-SELEX.

through a partition function (PF) algorithm (Zuker and Stiegler, 1981; McCaskill, 1990). However, it is also suggested that the predicted structures can be further augmented with reliability information to get more accurate structures.

Mfold is used to predict the secondary structures of RNA or DNA sequences (Zuker, 2003). Depending on the input sequence, mfold predicts a minimum free energy, ΔG , as well as the minimum free energies for all potential foldings. Over the years, new functions have been implemented such as the prediction of two state melting temperature and hybridization of two RNA or DNA strands.

Illustrative Examples and Case Studies

Previous experiments have demonstrated that the combination of SELEX, high throughput sequencing and bioinformatics can successfully identify aptamers for specific ligands such as LAG3 and TIM3 (Soldevilla *et al.*, 2017; Hervás-Stubbs *et al.*, 2016; Pei *et al.*, 2017; Eaton *et al.*, 2015). However, these identified aptamers were not reported to be riboregulators. The reason why the identified aptamers were not used as riboregulators because they are cytotoxic, insoluble, highly reactive and impermeable to cell membranes.

There are three aptamers identified via SELEX that have been reported as riboregulators namely the theophylline, tetracycline and streptomycin aptamers. The theophylline aptamer, can bind to theophylline with high affinity compared to other ligands and is the most prominent aptamer that can be manipulated as a riboregulator (Berens *et al.*, 2001; Wallace and Schroeder, 1998; Jenison *et al.*, 1994). The theophylline aptamer has been exploited to trigger expression via translation and transcription depending on the actuator domain (Wachsmuth *et al.*, 2013, 2015; Desai and Gallivan, 2004; Suess *et al.*, 2004). In 2004, a translational control element was carried out by cloning a theophylline aptamer upstream of the ribosome binding site of the reporter gene (Desai and Gallivan, 2004; Suess *et al.*, 2004). In 2013, the theophylline aptamer was fused to an intrinsic terminator thus creating a transcriptional riboregulator (Wachsmuth *et al.*, 2013). The secondary structure combination of the aptamer and actuator domains were analysed using the RNAfold program of the Vienna RNA package. The RNAfold program was used to calculate the free energy value and predict the secondary structure. The conformation of this aptamer has been studied extensively and shows a similar structure to the minimum free energy (MFE) predicted by RNAfold. The construct was able to terminate the expression of a reporter gene in the absence of theophylline. The same approach was used to design riboregulators using tetracycline and streptomycin as ligands (Domin *et al.*, 2017). The tetracycline and streptomycin aptamers were cloned into the 5' untranslated region of the *bgab* reporter. The aptamer responded to tetracycline and showed β -galactosidase activity.

Discussions and Future Directions

In the early 2000s, aptamers present in riboregulators were isolated *in vitro* and none of them were identified using SELEX/HT-SELEX analysis programs (Berens *et al.*, 2001; Wallace and Schroeder, 1998; Jenison *et al.*, 1994). The development of SELEX/HT-SELEX analysis programs had only started in early 2010 although the search for aptamers started 20 years ago. The programs can

be group into four strategies; i. sequence-structure motifs ii. statistical analysis iii. clustering and iv. multiplexer. The differences and similarities of each SELEX/ HT-SELEX analysis program are summarized in [Table 2](#).

In order to use these programs, they need to be installed together with their software dependencies. Fastaaptamer and MpBind are the only programs that do not require any additional software to be installed. Among these programs, FASTAaptamer is the most user friendly program. It requires only a basic knowledge of command line operations and the user's manual include the command line options. Advanced users can opt to integrate the analysis into a customized workflow or an existing sequence analysis pipeline ([Alam et al., 2015](#)).

However, to our knowledge, there are no known assessments that compare the efficiency, accuracy and speed of each program in analyzing SELEX or HT-SELEX data. It is necessary to examine more sensitive aptamers to a simple ligand so that they can be explored for eventual application riboregulator. The information obtained can be analyzed using the existing program. However, existing programs can be improved to make it easier to use and analyse data more accurately for shorter time.

Riboregulators generated from the mixing and matching of aptamer and actuator domains can work well with their specific ligands. To avoid false positives, a rationally designed riboregulator is evaluated through iterative design-build-test cycles. This is followed by global modelling of the RNA structure. As RNA sequence folds into secondary structure during transcription and this process is difficult to mimic *in vitro*, it is important to carry out the secondary structure prediction prior to actual synthesis of the candidates.

In the case of riboregulator design, it is suggested to use stochastic kinetic folding simulation approach ([Endoh and Sugimoto, 2015](#); [Thimmaiah et al., 2015](#); [Carothers et al., 2011](#)). In addition, an *in-silico* prediction method that can perform direct comparisons to *in-vivo* gene regulation activities through parallel assays should be developed ([Geertz et al., 2012](#)).

Closing Remarks

The construction of riboregulators via rational design can be a future conventional approach to analyse RNA sequences engaged in gene regulation. As more RNA data are made available, computational design of synthetic riboregulators provides a fast and cost-effective way to discover their potential applications in the organism of interest. However, the computational approaches should ideally be combined with laboratory evidence in order to best evaluate the versatility and functionality of the design.

Introduction

RNA is among the most versatile molecules in biology. While the information-encoding role of RNA has been known since the discovery of messenger RNA, research over the last three decades has uncovered functional roles for RNA in a vast range of processes (Cech and Steitz, 2014), including regulation of transcription, RNA splicing and editing, catalysis of protein synthesis (Nissen *et al.*, 2000), and control of chromatin structure (Khalil *et al.*, 2009; Názzer and Lei, 2014). To carry out its functions RNA must form secondary structures and fold into tertiary structures to bind small molecules and proteins, as well as to respond to environmental cues (Cruz and Westhof, 2009; Tinoco and Bustamante, 1999). Understanding these structures and how they form is essential for understanding how RNA performs its functions.

While the proper folding of RNA is crucial for its normal functions, RNA misfolding often leads to dysregulation and contributes to disease. For example, a large number of pathogenic RNA structures have been found in neurological diseases, including APP for Alzheimer's disease and -synuclein for Parkinson's disease with the formation of internal ribosome entry sites in mRNAs (Bernat and Disney, 2015). The motor neuron disease-associated RNA-binding proteins TDP-43 and FUS have been reported to function as RNA chaperones to ensure proper folding of repeat-associated RNAs for translation (Ishiguro *et al.*, 2017). Outside of neuroscience, a semiglobular ribozyme RNA can misfold into a dimer and activate the innate immune response protein, Protein Kinase R (PKR), providing a potential link between RNA misfolding and disease via innate immunity (Heinicke and Bevilacqua, 2012).

Here we consider RNA secondary structure to comprise regions of RNA base pairing, loops, and hairpins that form a hierarchical architecture (Cruz and Westhof, 2009), and tertiary structure to comprise the (often divalent cation-dependent) interactions between secondary structural units. Some recurrent structural features such as pseudoknots may be considered secondary structures despite not being strictly hierarchical, while loop-loop interactions involving Watson-Crick base pairing (Lee and Crothers, 1998) are usually considered tertiary structures.

X-ray crystallography and NMR spectroscopy have been used to determine numerous high resolution three-dimensional structures for both RNA and ribonucleoprotein complexes (Feigon, 2015; Westhof, 2015). Many now classic secondary structural patterns in RNA, such as the cloverleaf base pairing structures of tRNA (Kim *et al.*, 1974) and ultra-stable RNA stem loops (Cheong *et al.*, 1990) have been defined in three dimensions, while important new tertiary structural motifs have been identified and characterized (Devi *et al.*, 2015; Nissen *et al.*, 2001). Structure determination studies have also been used to dissect the detailed structural features of catalytic RNA function, such as the basis of polypeptide bond formation in protein synthesis (Nissen *et al.*, 2000) and the nuclease function of RNase P (Reiter *et al.*, 2010).

The size and flexibility of many RNA molecules, however, make determination of their full three dimensional structures impossible. RNA molecules undergo dynamic changes in structure over an enormous range of timescales, and large RNA molecules are often best described as an ensemble of structures (Mustoe *et al.*, 2014). Refolding of RNA molecules *in vitro* is highly dependent on experimental conditions and at best can represent only a subset of the dynamic conformations assumed by RNA in the cell. In addition, RNA functions are both so widespread and so dynamic that they need to be understood in concert across the genome in addition to being determined one structure at a time.

Secondary structure prediction applications are discussed elsewhere in this volume need cross-reference and have been greatly aided by improved thermodynamic rules from experimental studies as well as algorithms to enumerate multiple structures from a thermodynamic ensemble (Mathews and Turner, 2006). Free energy minimization of secondary structure from sequence, however, is far from perfect, and is greatly improved by structural constraints provided by experimental data (Hajdin *et al.*, 2013; Mathews *et al.*, 2004).

A widely used and powerful approach for interrogating RNA structure is to challenge RNA molecules in solution with structure-dependent chemical or enzymatic probes. Structural probing experiments can identify regions of sequence that are accessible to cleavage or modification, and thus infer which nucleotides are more likely to be double stranded, single stranded, flexible, constrained, or involved in tertiary interactions. The traditional approach is a form of footprinting experiment: treating an RNA with a reagent to induce modification or cleavage, and then detecting termination of reverse transcription (RT) products on a polyacrylamide gel. A simple interpretation is for the footprints (indicating termination of RT) to be evenly distributed and more prevalent along the unfolded stretches of sequence. The termination positions are determined by polyacrylamide gel electrophoresis and quantitative analysis from the changes of footprint on, say, unfolding. Thus, it is possible to detect location of the secondary and tertiary structure of RNA (Peattie and Gilbert, 1980).

While powerful, conventional RNA structure probing approaches have also suffered from severe limitations. Enzymatic probes and many chemical probes cannot be employed for *in vivo* studies, and traditional chemical probes are dependent on the RNA sequence as well as structure. RNA molecules are interrogated one species at a time. Using conventional polyacrylamide gels to analyze RT termination severely restricts the size of RNA fragments that can be analyzed, and interrogates only the first modified position of any RNA molecule. Finally, traditional probing methods examine structure features at individual sequence positions, but are unable to directly interrogate long range interactions, which form the vast majority of RNA secondary and tertiary structure.

Advances over the last decade are removing all of these limitations. Selective 2'-hydroxyl acylation and primer extension (SHAPE) chemistry makes it possible to probe RNA flexibility at single nucleotide resolution independent of nucleotide identity (Merino *et al.*, 2005). Capillary electrophoresis increases the size and throughput of structure probing experiments over conventional gels (Mitra *et al.*, 2008; Wilkinson *et al.*, 2008). Conditions that convert adducts to mutations during reverse transcription allow measurement of correlated modifications at multiple positions (Siegfried *et al.*, 2014; Zubrady *et al.*, 2016). High throughput sequencing technology makes it possible to simultaneously interrogate large numbers of RNAs, even whole transcriptomes, in a single experiment (Kwok, 2016). Finally, direct chemical probes of base pairing make it possible to interrogate long range interactions *in vitro* and *in vivo* (Aw *et al.*, 2016; Lu *et al.*, 2016; Sharma *et al.*, 2016).

Computational innovations have accompanied each new experimental advance. New computational methods and bioinformatics resources not only help researchers interpret high throughput data from new experimental technologies, but also help to improve predictions of RNA folding using both hard and soft constraints supplied from experiments. One happy result is that databases have arisen to store and organize the increasing output of RNA structure probing studies, and now make structure probing results openly available to researchers. The vast increase in structural data is creating new opportunities to understand the rules of RNA folding.

Background

Chemical and Enzymatic Structure Probing of RNA

Both chemical reagents and nucleases can be used as structure-dependent probes by cleaving RNA or creating covalent modifications that can be detected by subsequent cleavage and direct labeling or primer extension (Ziehler and Engelke, 2001). Chemical probes of RNA structure have been used for RNA footprinting studies since 1980 (Peattie and Gilbert, 1980). The widely used chemical probe dimethyl sulfate (DMS), for example, methylates the N1 of adenine, the N7 of guanine, and the N3 of cytidine. When a reverse transcriptase is used to generate a cDNA from a DMS-modified RNA, the primer extension halts opposite modified A and C nucleotides; the first modified position is identified via polyacrylamide gel electrophoresis. Since the positions methylated by DMS are directly involved in double stranded base pairing, accessibility to DMS modification is a surrogate measure of single-stranded A and C positions (Tijerina *et al.*, 2007).

A number of other base-specific probes are used besides DMS to interrogate RNA secondary structure. For example, kethoxal modifies guanines and CMCT can modify U or G; these modifications only occur at single-stranded regions and so can be used as probes of secondary structure (Brow and Noller, 1983; Ho and Gilham, 1971). When multiple chemical probes with different specificities are used in a combination of experiments, base-specific chemical probes can interrogate every position of an RNA molecule, but individual probes that modify base moieties are inherently sequence-dependent.

For many years the only sequence-independent chemical probe in widespread use was hydroxyl radical (Tullius and Greenbaum, 2005), which leads to RNA cleavage at positions where the RNA backbone is accessible to solvent. In 2005, Kevin Weeks' team introduced a new structure probing chemistry called SHAPE that modifies the ribose moiety of an RNA molecule (Merino *et al.*, 2005). A SHAPE reagent probes nucleotide flexibility by esterifying the 2' position of a nucleotide; the reaction is inhibited by a conformationally constrained 3' phosphodiester, and so SHAPE serves as a conformational probe of RNA. Much like DMS modifications at A and C nucleotides, SHAPE modifications halt reverse transcription so that termination products can be detected on polyacrylamide gels, but unlike DMS, SHAPE can interrogate every position of an RNA sequence. DMS and SHAPE reagents are the two most widely used chemical probes of RNA structure.

While the examples above are chemical, nucleases can also function as probes of single-stranded or double-stranded RNA. Many RNases used for such experiments are base-specific (Knapp, 1989), but some more recently used endonucleases show little base specificity *in vitro* (Daou-Chabo and Condon, 2009). It should be noted that depending on enzymatic reactions for RNA structure may introduce additional dependencies such as steric accessibility of enzyme-substrate interactions.

High-Throughput Structure Probing and Automation

The throughput of RNA footprinting was dramatically improved by combining DMS and SHAPE probes with capillary electrophoresis (CE) (Mitra *et al.*, 2008; Wilkinson *et al.*, 2008), and developing automated algorithms to process and quantify chemical reactivities at single-nucleotide resolution (Mitra *et al.*, 2008; Vasa *et al.*, 2008). Capillary electrophoresis also greatly increased the size of individual RNA molecules that could be analyzed by structure probing experiments, limited by the capillary electrophoresis itself and the software's ability to align the electrophoretic signal to sequence, correct for drop-off over the length of sequence, and convert to per-nucleotide reactivities. The underlying methods are not only applicable to RNA structure studies, but for footprinting protein binding sites to RNA.

The increased throughput of capillary electrophoresis and automation applied to RNA structure probing provided a major step towards genome-scale probing of RNA structure. In addition to the technology development and invention of CE-SHAPE, Wilkinson *et al.* (2008) identified structural properties of the HIV genome that would later be recapitulated and extended in later

Fig. 1 .Schematic diagram of NGS-based genome-wide probing of RNA structure. The sample of an RNA population with secondary structure is split evenly into control and experiment. In experimental RNA sample, the particular structured nucleotides (double stranded or single stranded) are probed through enzymatic cleavage or chemical modification. These probing nucleotides terminate RT or introduce point mutations at the probing sites. Both control and experimental samples are processed for cDNA library preparation and NGS. The RT stops or mutations are counted on each nucleotide in experimental sample and normalized against the control. By identifying the probing signals (RT stops or mutations), the structure of each nucleotide is determined.

genome wide studies, such as the conservation of structural domains across different biological states, quantitative differences in structure between coding and non-coding regions, high levels of structure in regulatory RNA sequences, and identification of RNA recognition motifs for protein binding in intact biological systems. CE-SHAPE was also essential for the first whole-genome RNA structure studies of retroviruses such as the HIV genome (Watts *et al.*, 2009), which identified not only the secondary structure of HIV but important links between RNA structure and protein coding.

RNA Structure Probing With Deep Sequencing

Both conventional and capillary electrophoresis-based structure probing extend primers from defined sites, often combined with a structure “cassette” to ensure processivity of the reverse transcriptase. Next-generation sequencing (NGS) technology dramatically increased the potential for whole-genome studies (Aviran *et al.*, 2011; Kertesz *et al.*, 2010; Lucks *et al.*, 2011; Underwood *et al.*, 2010) of RNA structure by allowing simultaneous measurement of hundreds or thousands of RNA molecules. Rather than using labeled primers as in capillary electrophoresis, double stranded cDNA libraries are prepared after enzymatic or chemical

Table 1 Methodological advances towards genome-wide probing of RNA structure

Method	Probe	Structural specificity	Sequence specificity	Detection of probing site	RNA status	Milestone	Reference
PARS	Nuclease S1	ssRNA	None	RT stop	<i>In vitro</i> ; native deproteinized	Detection of both ss and ds RNA; genome-wide	Kertesz <i>et al.</i> (2010)
FragSeq dsRNA-seq	RNAse V1	dsRNA				Structure probing with enzymatic probe	Wan <i>et al.</i> (2012), Wan <i>et al.</i> (2013, 2014)

ssRNA-Seq SHAPE-seq; Shape-seq 2.0	RNAase V1	dsRNA			<i>In vitro</i>	NGS combined with SHAPE probing; rigorous model for intensity drop-off	Lucks <i>et al.</i> (2011), Loughrey <i>et al.</i> (2014)
	NMIA; 1M7	ssRNA	None	RT stop	<i>In vitro</i>	Genome-wide <i>in vitro</i> structure probing; Circularization libraries	Rouskin <i>et al.</i> (2014)
DMS-seq	DMS	ssRNA	A, C	RT stop	<i>In vitro</i> ; denatured	Genome-wide <i>in vitro</i> structure probing	Ding <i>et al.</i> (2015)
	DMS	ssRNA	A, C	RT stop	<i>In vitro</i> ; <i>in vitro</i>	Genome-wide <i>in vitro</i> structure probing	
Structure-seq	DMS	ssRNA	A, C	mutation	<i>In vitro</i>	Genome-wide RNA structure mutational profiling <i>in vivo</i> ; circularization libraries	Zubradt <i>et al.</i> (2016)
DMS-MaPseq	DMS	ssRNA	A, C	mutation	<i>In vitro</i>	Detection of long-range interactions and correlations reflecting distinct conformations	Homan <i>et al.</i> (2014)
RING-MAP	DMS	ssRNA	A, C	RT stop	<i>In vitro</i>	High-throughput sequencing for structure probing with long RNAs	Talkish <i>et al.</i> (2014)
Mod-seq	DMS	ssRNA	A, C	RT stop	<i>In vitro</i>	two probes cover all four nucleotides	Incarnato <i>et al.</i> (2014, 2015)
CIRS-seq	DMS; CMCT	ssRNA	A, C; G, U	RT stop	Native deproteinized	Enable the detection of low-abundance RNAs	Siegrfried <i>et al.</i> (2014)
SHAPE-MaP	NMIA; 1M7	ssRNA	None	mutation	<i>In vitro</i>	Modified SHAPE reagent to penetrate cell; Use biotin conjugation on probes to enrich probed RNAs	Spitale <i>et al.</i> (2015)
icSHAPE	NAI-N3	ssRNA	None	RT stop	<i>In vitro</i> ; <i>in vitro</i>	Use psoralen derivative to penetrate cell and cross-link dsRNA	Lu <i>et al.</i> (2016)
PARIS	AMT (psoralen)	dsRNA	None	Cross-links	<i>In vitro</i>	Ligation after cross-link to study RNA-RNA interactions	Sharma <i>et al.</i> (2016)
LIGR-seq	AMT (psoralen)	dsRNA	None	Cross-links	<i>In vitro</i>	Enrichment on streptavidin beads	Aw <i>et al.</i> (2016)
SPLASH	biopsoralen crosslinking	RNA-RNA interactions	None	Cross-links	<i>In vitro</i>		

modification with adapter sequences added at both ends for paired end deep sequencing (Fig. 1). The additional steps, such as conversion of the modified RNA to cDNA and preparation of the library with adapters for sequencing, add additional sources of bias and variation to the resulting signal that need to be addressed by some combination of experiment and analysis. A summary of advances is shown in Table 1.

Genome-Wide Enzymatic Probing Methods

Enzymatic probes were first used for genome-wide next-generation RNA structure probing in 2010. The methods differ in a variety of ways, as well as in their applications, but all share a common outline of *in vitro* RNA isolation, cleavage with structure-specific enzymes, adapter ligation and library preparation, and paired end sequencing.

In the development of FragSeq, Underwood *et al.* (2010) used endonuclease P1 from *Penicillium citrinum* to cut RNA preferentially at single stranded regions. RNAase P1 cleaves RNA to leave a 5' phosphate and 3' hydroxyl, features which were exploited in the adapter ligation steps of the method. True RNAase P1 digestion products were distinguished from both endogenous 5' phosphate-containing RNAs and endogenous breaks by comparing experimental libraries to control libraries prepared from undigested RNA or RNA treated with polynucleotide kinase + ATP, respectively. The authors developed a "cutting score" to interpret FragSeq data, and while they initially validated and calibrated the method on *in vitro* RNA molecules with known secondary structure, they also applied it to the entire mouse nuclear transcriptome.

In dsRNA-seq, Zheng *et al.* (2010) focused on double stranded regions of RNA from *Arabidopsis* in order to identify novel substrates of the RNA-dependent RNA polymerase 6 (RDR6), which synthesizes dsRNA during small RNA biogenesis. Unlike the other methods described here, the dsRNA-seq approach does not interrogate individual nucleotides for their structure-specific cleavage, but isolates and sequences fragmented double-stranded RNA after enzymatic depletion single stranded RNA regions.

In PARS, Kertesz *et al.* (2010) used two different enzymes with different structural specificities: RNAse VI cleaves 3' of double stranded nucleotides and endonuclease S1 specific for single stranded regions. Like FragSeq, the cleavage products contain 5' phosphates at the cleavage site and so adapter ligation is specific to this expectation. A "PARS score" is set as the log ratio of sequence reads for each nucleotide after V1 and S1 cleavage, and thus a high PARS score reflects a higher likelihood of being double stranded. The original PARS study was applied to the entire yeast transcriptome, validating known structures and characterizing previously unknown structures. Interestingly, coding regions of mRNA were more structured on average than flanking UTR sequences.

Rigorous Computational Models of High-Throughput Structure Probing Data

SHAPE provides nucleotide flexibility information at single-nucleotide resolution. The heuristic models of reverse transcriptase drop-off used for SHAPE-CE are insufficient for comprehensive analysis of next generation sequencing platform data, so for SHAPE-seq (Lucks *et al.*, 2011). Aviran *et al.* (2011) developed a rigorous maximum likelihood model for the experimental process of chemical probing followed by paired end deep sequencing. The SHAPE-seq model includes parameter estimates for the natural drop-off propensity at each nucleotide in a transcript, which is itself a property of local structure and so varies along the sequence. The chemical modification model represents the number of exposures of an RNA to an electrophile as a Poisson process. The conditions of RNA structure probing experiments are generally designed to favor single-hit kinetics, corresponding to a Poisson rate process $c \approx 1$, but under such conditions many molecules are not exposed to electrophiles at all and a significant proportion will experience multiple modifications. By incorporating the ML estimate of the natural drop-off and developing an efficient optimization procedure for the model parameters, the authors were able to obtain per-nucleotide reactivity estimates that both supported the use of deep sequencing technology for highly parallel structure probing and provided a theoretical framework to improve existing methods.

In Vivo Chemical Probing of RNA

Enzymatic probing approaches are largely limited to *in vitro* studies of RNA structure, which does not directly interrogate the state of RNA in the cell. *In vitro* probing studies also require additional preparation steps that can alter RNA structure or intentionally re-fold RNA molecules prior to interrogation. Chemical probes have the potential to penetrate the cell for *in vivo* measurements. DMS has been used to probe RNA in cells since at least 1998 (Luo *et al.*, 1998). The original SHAPE reagents react with the hydroxyl group of water, which obviates the need to quench the reaction, but relatively long reaction times prevents the SHAPE reagent NMIA from being used in intact cells. Two SHAPE reagents designed for use *in vivo* studies (NAI and FAI) were developed (Spitale *et al.*, 2013) with high solubility and reactivity; along with some use of 1M7, these reagents make *in vivo* SHAPE experiments more accessible.

Whole transcriptome *in vivo* chemical probing was further advanced with the development of icSHAPE (Flynn *et al.*, 2016), in which the NAI reagent designed for *in vivo* SHAPE was further modified by addition of an azide (NAI-N₃). Any genome wide *in vivo* profiling of RNA structure must contend with the overwhelming proportion of unmodified RNA sequence; the azido moiety on NAI-N₃ is used in a 'click' reaction to attach biotin at the modified nucleotide, and thus enrich the RNA for modifications by isolation on streptavidin beads.

Beyond One Modification Per RNA Molecule

Mutational profiling (MaP)

Identifying modification sites by truncation of reverse transcription identifies the first modified nucleotide encountered by reverse transcriptase, and necessitates conditions of one-hit kinetics. This limitation prevents the detection of correlated modifications in single RNA molecules which would give insights into alternative structures and long range interactions. To overcome this limitation, conditions of reverse transcription have been developed that allow SHAPE modifications to be read through and converted into mutations (Smola *et al.*, 2015). The result is a mutational profile, or MaP, that encodes chemical modification in sequence, thereby simplifying the library preparation steps for highly parallel sequencing, gaining accuracy for low abundance RNAs, and allowing in principle the measurement of multiple modifications in single molecules.

Multiple types of mutations are created in SHAPE-MaP experiments, so the interpretations of data is handled differently from traditional CE-SHAPE or SHAPE-seq. Software for interpreting SHAPE-MaP data (Busan and Weeks, 2018) is designed to account for the different types of mutations, including possibly ambiguous reads, in order to estimate reactivities for each nucleotide with more precision than conventional SHAPE.

Mutational profiling can be performed with DMS as well as with SHAPE reagents (Homan *et al.*, 2014; Zubradt *et al.*, 2016). Homan *et al.* (2014) used a DMS-MaP approach with conditions optimised to produce multiple modifications per RNA molecule and identify RNA interactions groups, or RINGs. The interacting groups are observed as correlated mutations from either dynamic “breathing” of RNA structures (thus identifying through-space interactions) or multiple distinct structures taken by a molecule. To identify the underlying structures, the correlated reactivities can be subjected to spectral decomposition into distinct clusters; each cluster can be modeled as arising from a distinct structural form. Interestingly, the RING-MaP approach makes it possible to characterize ligand-dependent conformational changes in riboswitches, as well as underlying structures in ensembles more generally.

Combining systematic mutation with chemical probing

An alternative approach to long range interactions is to combine structural probing with systematic mutation of a target RNA molecule. Since mutations at base paired nucleotides are likely to increase the flexibility of its normal pairing partner, a two-dimensional “mutate-and-map” strategy can identify base pairs with high precision (Kladwang and Das, 2010; Kladwang *et al.*, 2011). The systematic mutation approach of mutate-and-map adds precision to DMS and SHAPE profiling experiments, and can be used to infer long range interactions (Tian *et al.*, 2014).

Direct determination of long-range interactions

RING-MaP and mutate-and-map data provide important indirect inference of long range interactions from structure probing experiments. In 2016, three groups simultaneously developed methods for *in vivo* profiling of long range RNA interactions using variations of psoralen crosslinking (Aw *et al.*, 2016; Lu *et al.*, 2016; Sharma *et al.*, 2016). Derivatives of the small molecule psoralen have long been used to cross-link RNA. For *in vivo* cross-linking, psoralen has favorable properties: psoralen intercalates at base-paired nucleotides, some derivatives readily enter cells, and psoralen forms reversible cross-links across double-stranded RNA after illumination at 365 nm.

In LIGR-seq, Sharma *et al.* (2016) used AMT, psoralen variant that readily penetrates cells, to cross-link RNA followed by endonuclease digestion and proximity ligation to identify interactions by paired end sequencing. They applied LIGR-seq to HEK-293 cells and were able to identify both known and novel interactions involving non-coding RNAs, and highlighted a surprising number of interactions for the orphan snoRNA SNORD83B. In PARIS, Lu *et al.* (2016) also used AMT for cross-linking, but enriched the cross-linked regions with 2D gel electrophoresis. The results are discussed below as one of the case studies of genome-wide RNA structure probing. In SPLASH, Aw *et al.* (2016) used a biotinylated psoralen for cross-linking. The use of biotinylated psoralen required a mild detergent to increase cellular uptake in mammalian cells and in yeast, but enabled enrichment of crosslinked regions using streptavidin beads. The SPLASH study identified a number of clear structural properties of classes of RNA, such as the long range intramolecular interactions within UTRs of mRNAs, and newly identified interactions between snoRNAs and rRNA.

Direct detection of RNA interaction in helices is a major step forward for genome-wide RNA structure studies. Each of the methods described above uses proximity ligation and high-throughput paired end sequencing to determine gapped reads that represent long range interactions through base pairing. While most of the mapped reads are ungapped, possibly due to limitations of the proximity ligation, the sensitivity and power of direct interaction methods dramatically increase the capabilities of RNA structure probing methods.

Example Applications

Genome wide profiling RNA structure profiling applications are expanding rapidly. Here we briefly review two studies that provide some indication of how much insight these experiments can provide.

Genome Wide Measurement of RNA Unfolding

The melting temperature of a double stranded RNA molecule has long been used as a measure of folding stability. RNA unfolding is conventionally measured by change in UV absorbance. [Wilkinson *et al.* \(2005\)](#) first combined RNA structure probing with temperature-driven unfolding to determine the temperature dependence of structural interactions in the unfolding of a tRNA^{Asp} transcript. [Wan *et al.* \(2012\)](#) used the PARS approach with RNase V1 to determine the melting temperature per base across the yeast genome by a method they termed Parallel Analysis of RNA structures with Temperature Elevation (PARTE). PARS had already been used for genome-wide analysis of the yeast transcriptome, and RNase V1 was shown to retain its specificity for double stranded RNA up to 75°C, so it was possible to develop conditions for single-hit kinetics with PARS over a range of temperatures after *in vitro* RNA refolding.

A computational method for estimating T_m values for individual nucleotides was developed along with PARTE and used to estimate the T_m values for over 350,000 bases in the yeast transcriptome. When these T_m values were averaged per gene to generate an estimated melting temperature (eT_m) per gene, the eT_m values were moderately concordant with UV-measured T_m values of randomly chosen short transcripts, and more highly concordant for those transcripts with the most read coverage. The eT_m values were also correlated with T_m values predicted using RNAfold, but showed marked deviations for some molecules, suggesting that experimental temperature-dependent structure probing data could be used to improve RNA unfolding predictions much like ordinary structure probing data are used to constrain predicted RNA secondary structures.

The PARTE analysis made it possible to associate RNA folding energy with RNA feature annotations. Noncoding RNAs, for example, showed both more highly stable bases (T_m > 75°C) and higher eT_m values than mRNAs. Among mRNA transcripts, the coding sequence (CDS) appears to be more structured than the 5'-UTR and 3'-UTR regions, as had been shown earlier ([Kertesz *et al.*, 2010](#)). However, the PARTE analysis also identified a polarity of structural features (local eT_m) within mRNAs that demarcated the CDS and could not be explained by GC content alone: the most meltable region of mRNA is -3 to +3 nucleotides around the start codon and the most stable paired region is 20 nucleotides immediately upstream and 10 nucleotides immediately downstream of the stop codon. Interestingly, structural stability at the start of the CDS showed a weak inverse correlation with translation rate.

The PARTE analysis identified known and putative RNA functional elements by virtue of their structural stability. Very stable structures in 3'-UTRs, for example, included known structures directly involved in heat shock response, while 5'-UTRs were enriched in structures with lower eT_m (30–37°C) and highly enriched for genes whose expression decreased in heat shock transcriptional profiling experiments, suggesting that these low eT_m structures may function as RNA thermometers. Indeed, when RNAs were binned by eT_m values, the least stable RNAs (with eT_m 26–40°C) were predictive of the pattern of heat shock-induced *in vivo* RNA decay. The authors propose, and show data to support, that these less structured RNA regions may function as RNA thermometers of RNA decay by blocking exosome processing at low temperature. Increasingly stable RNA structures progressively blocked exosome processing, indicating the exosome recognizes unpaired bases to degrade RNAs that unfold during heat shock.

Phylogenetic Conservation of Directly Observed Duplexes

DMS-seq, structure-seq and icSHAPE have all been used to identify single-stranded regions of RNA *in vivo* by chemical probing of flexible or unpaired bases ([Ding *et al.*, 2014](#); [Rouskin *et al.*, 2014](#); [Spitale *et al.*, 2015](#)). However, while these methods provide constraints on the structure at individual nucleotide positions, they do not provide any direct information about long range interactions. [Lu *et al.* \(2016\)](#) used psoralen probing of RNA duplex in living cells, termed PARIS (psoralen analysis of RNA interactions and structures) to identify long range interactions directly via paired end sequencing (see Section “Direct Determination of Long-Range Interactions” for a discussion of the method itself).

Conservation and covariation of duplex structures

[Lu *et al.* \(2016\)](#) performed PARIS in two human cell lines (HeLa and HEK293T) and in mouse embryonic stem (mES) cells, and identified duplex groups (DGs) from gapped reads. A substantial proportion DGs spanned much larger regions of sequence (> 1000 bp) than normally identifiable or predictable, which offers new opportunities to investigate structure conservation and covariation ([Smith *et al.*, 2013](#)). By directly pairing the helices observed in DGs for human and mouse data, [Lu *et al.* \(2016\)](#) were able to perform covariation analysis on structures conserved between human and mouse, and use the PARIS-identified helices along with icSHAPE data to guide a much broader phylogenetic analysis of conserved structures.

Long range interactions are typically ignored in such structure covariation analysis because of the computational complexity of an unconstrained search; the PARIS constraints make it possible to focus directly on covariation at observed structural interactions, regardless of the distance between the paired sequence arms. In addition, PARIS data make it possible to avoid incorrectly assigned covariation searches that naturally become the focus of an unconstrained analysis.

Distinguishing between alternative RNA structures

As discussed in Section “Beyond One Modification Per RNA Molecule”, one-dimensional structure probing data using single-hit kinetics infers only an average reactivity, even if multiple alternative RNA structures exist. Mutational profiling, correlation methods, and mutate-and-map strategies provide information about dynamics and alternative structures important for RNA structure-function relationships. PARIS also provides precise information about alternative structures, which can be directly

detected as duplexes that are mutually incompatible. The authors analyzed the 50 mRNAs with the most detected helices as candidates for alternative structures: about 20%–50% of DGs from these mRNAs were found involved in at least one pair of alternative structures, suggesting that alternative structures are pervasive. The result also suggests that direct duplex detection can be used to identify functional RNA conformational switches such as riboswitches and RNA thermometers.

Higher order structure of XIST lncRNA in epigenetic silencing

PARIS, icSHAPE and phylogenetic conservation were combined to determine the higher order structure of XIST, a 19kb lncRNA essential for X chromosome inactivation, but whose structure has been contested. Global PARIS data revealed both local duplexes and multiple long-range interactions in the XIST lncRNA in what appear to be four structural domains. Phylogenetic analysis showed conservation of a subset of PARIS-determined helical structures, consistent with a functional role for three of the four domains.

An intriguing feature of XIST is the A-repeat, a spaced multicopy conserved sequence at the 5' end of the XIST RNA. Previous data had shown that the A-repeat is not required for XIST to coat the X chromosome in mouse, but is required for epigenetic silencing. The A-repeat had also been shown to be required for XIST RNA binding to the Spen protein, which provides an appealing link to epigenetic silencing. The A-repeat structure was difficult to determine, however, in part because of its repetition, and in part because of the limitations of conventional structure probing data and associated computational predictions.

The PARIS data indicate that the A-repeat region forms an isolated domain with extensive inter-repeat interactions, between the first halves of repeats, and mostly between neighboring repeats. The structure of inter-repeat units from PARIS is consistent with the icSHAPE data, and suggest that the A-repeats in XIST form a higher order structure. Since previous data had shown that Spen did not show any preference for single A-repeat units (Monfort *et al.*, 2015), it was possible that higher order structure was required for Spen RNA binding. Lu *et al.* (2016) performed iCLIP experiments to test this and found that Spen interacted virtually exclusively with the single stranded spacer regions between A-repeat units, suggesting that the A-repeat domain RNA architecture facilitates Spen binding.

Challenges and Future Directions

In this article, we have discussed the experimental and computational approaches for genome wide, next-generation sequencing-based RNA structure probing. The expanding repertoire of experimental RNA probing studies, now able to interrogate long range interactions as well as individual nucleotide positions, provide data for constraint based RNA folding algorithms that greatly exceed the performance of unconstrained folding predictions. Scientists in the field are taking advantage of these emerging technologies to provide tools and resources for the broader scientific community.

Many of the individual labs cited in this article have developed software for processing chemical probing data and producing reactivities or predictions as described in their papers. The full list is too numerous to describe here, but the citations above and the summary of Table 1 are meant to provide a brief guide.

Constraints and Databases

RNA folding and prediction models that include constraint from experimental probing data are rapidly improving. The power of such constraints has been recognized for some time (Deigan *et al.*, 2008; Low and Weeks, 2010; Weeks, 2010), but techniques such as mutate-and-map (Kladwang *et al.*, 2011) SHAPE-MaP (Smola *et al.*, 2015), and direct duplex probing methods add a great deal of power to the available constraints. Computational methods for incorporating those constraints into folding prediction continue to advance (Lorenz *et al.*, 2016; Rice *et al.*, 2014), including recent extension to homologous sequences (Tan *et al.*, 2017).

Making use of such data requires it to be organized and accessible. The FoldAtlas database (Norris *et al.*, 2017) and Structure Surfer (Berkowitz *et al.*, 2016) are intended as a comprehensive archive of RNA structure probing data. FoldAtlas includes a focus on mutate-and-map studies.

The combination of high-throughput sequencing, innovative library preparation, and rigorous computational models is rapidly creating a new understanding of RNA structure *in vitro* and *in vivo*. The development of *in vivo* probing methods is exciting for many reasons, not least because it has suggested that RNA may be less structured in the cell than often observed in the tube. It is tempting to think that whole genome RNA probing technology may obviate the need for more focused structure probing studies, but this is unlikely to be the case: focused methods such as mutate-and-map interrogate target RNAs in depth and provide unique insight into sequence-structure relationships.

Emergence of Single-Molecule Sequencing Technologies

Virtually all of the recent sequencing studies for RNA structure probing have utilized “next-generation sequencing” that provide tens of millions of relatively short paired end reads. Using this high-throughput sequencing technology for RNA structure studies

has required development of innovative library generation protocols; the protocols can be complex, but are a basic requirement of the sequencing technology. Furthermore, termination-based structure profiling is limited to one modification per molecule. While mutational profiling (MaP) approaches can read multiple modifications of a single molecule they are still limited by the underlying sequencing technology and library preparation requirements.

Recently developed single molecule sequencing technologies have been reported to read extremely long DNA and RNA sequences (Garalde *et al.*, 2018; Jain *et al.*, 2018), and can in principle directly detect covalent modifications of individual nucleotides (Vilfan *et al.*, 2013). This exciting capability has the potential to eliminate the library preparation requirements of current structure probing methods. Indeed, it seems inevitable that the next era of RNA structure probing studies will use single molecule direct sequencing of chemically modified RNAs to combine the best features of chemical probing and mutational profiling, detecting numerous modifications of single RNA molecules read across their entire lengths.

Biographical Sketch

Xiaojing Huo is a postdoctoral research fellow in Prof. Greg Tucker-Kellogg's at the National University of Singapore. She did her PhD training in functional genomics and RNA-seq studies of tumorigenesis models in zebrafish. Her current research interest is on dissection of TGF β signaling in models of human cancers.

Jeremy Ng is a graduate student in computational and molecular biology at the National University of Singapore. His research interest is the regulation of TGF β signaling axis decisions following ligand exposure.

Tan Mingchen is a PhD candidate in computational biology at National University of Singapore. His research a Prize Collecting Steiner system to dissect regulatory networks from heterogeneous genomic data.

Greg Tucker-Kellogg is Professor in Practice in the Department of Biological Sciences and Director of the Faculty of Science Computational Biology Program at the National University of Singapore. He received his PhD in from Yale University under Peter Moore, and was a Jane Coffin Childs Postdoctoral Fellow at Harvard Medical School with Christopher T. Walsh. Prior to joining the NUS faculty, he spent nearly 15 years in the biotech and pharmaceutical industries. His laboratory is developing tools for both optogenetic regulation of cancer signaling pathways and for measurement of single-cell chromatin dynamics.

Assessment of Structure Quality (RNA and Protein)

Introduction

Knowledge of the three-dimensional structure of biological molecules has been a permanent goal and often a breakthrough achievement in modern science. Structural (molecular) biology has developed since the late 1950s and now constitutes one of the major forces of scientific progress; for an exciting account on the history of the field by some of its key players, see [Nature Structural and Molecular Biology \(2011\)](#). Among these were [Kendrew *et al.* \(1958\)](#), who first published the structure of myoglobin by X-ray analysis. The application of this technique to determine the tertiary structure of proteins as rigid solids has brought about a revolution in structural biology. Ever since, more than 130,000 protein structures have been resolved at atomic resolution by different techniques and deposited in the publicly available Protein Data Bank (PDB) ([Berman *et al.*, 2000](#)). Nuclear magnetic resonance (NMR) spectroscopy has allowed the determination of dynamic protein structures in solution or in membranes since the late 1970s ([Wüthrich, 2001](#)). Small angle scattering of neutrons (SANS) and X-rays (SAXS) provide means to study the size and shape of proteins ([Mertens and Svergun, 2010](#)). These techniques can be applied jointly with X-ray crystallography ([Tsutakawa *et al.*, 2007](#); [Wang and Wang, 2017](#)) or NMR ([Hennig and Sattler, 2014](#)) to analyze tertiary structures, including those of flexible proteins or large complexes. More recently, cryo-electron microscopy (cryo-EM or simply EM) has been successfully applied to reveal the structures of proteins that could not be determined by other means, although generally at a lower resolution ([Bai *et al.*, 2015](#)). Despite the valuable advances in the field, protein structure determination remains a challenging endeavour, due to high associated costs, experimental constraints like the need for overexpression and purification of the sample and certain properties of some proteins such as highly flexible disordered regions.

The methodologies for high-quality, atomic-resolution RNA structure determination are similar to those applied for proteins ([Felden, 2007](#)). X-ray crystallography and NMR spectroscopy can provide detailed information about RNA in solid phase or in solution, respectively, with cryo-EM still offering lower resolution structures. However, general interest in RNA biology developed later than for proteins and our knowledge of the field is comparatively restricted. To date, the Protein Data Bank ([Berman *et al.*, 2000](#)) lists 1297 RNA-only structures and 2067 RNA-protein complexes, most of them also linked in the Nucleic Acid Database ([Coimbatore Narayanan *et al.*, 2014](#)). These represent barely 2.5% of the total PDB entries as of September 2017, with a steady pace of 30–81 new structures deposited per year in the last two decades. This scarcity must also be related with intrinsic experimental difficulties such as dealing with a vast RNA backbone conformational space ([Murray *et al.*, 2003](#)). Besides the possibility of determining the position of its atoms, low-resolution RNA structure analysis can be performed by other experimental methods such as different *in vivo* and *in vitro* structure-specific chemical and enzymatic probes of base pairing and interactions ([Kubota *et al.*, 2015](#)), or the selective 2'-hydroxyl acylation analyzed by primer extension (SHAPE) ([Weeks and Mauger, 2011](#)) for detecting unconstrained, flexible positions.

Experimental procedures for the determination of protein or RNA three-dimensional structure include a final step of quality control and model refinement. The worldwide Protein Data Bank (wwPDB) has provided in-house tools for deposition and annotation of protein and nucleic acid structures ([Dutta *et al.*, 2009](#)), including the PDB Validation Suite ([Westbrook *et al.*, 2003](#)) for curation and validation of submissions, that recently converged in the unified OneDep system ([Young *et al.*, 2017](#)). The agreement between diffraction data and the atomic coordinates of the final model is typically measured by the R-value criterion of accuracy and by the less biased and more reliable R_{free} cross-validation statistical ([Brünger, 1992](#)). Model-to-data quality of fit, plus the geometric and stereochemical properties of solved structures, can also be evaluated with external, standalone tools such as the PHENIX crystallographic software ([Adams *et al.*, 2010](#)) and PROSESS (Protein Structure Evaluation Suite & Server) ([Berjanskii *et al.*, 2010](#)). Moreover, PROCHECK ([Laskowski *et al.*, 1993](#)), WHAT_CHECK ([Hooft *et al.*, 1996](#)) and MolProbity ([Chen *et al.*, 2010](#)), among others, seek to assess how far the properties of experimental or computational structures are from those observed in known structures. Even after quality checks and improvements, many solved structures are neither complete nor free from errors, and although X-ray crystallography models are generally acceptable, there is still inconsistency in terms of resolution and quality measures in the PDB ([Domagalski *et al.*, 2014](#)).

Regardless of the methodology and despite the many advances in the field, experimental structure determination remains a challenging task for many reasons, including high associated costs in materials and manpower, experimental constraints like sample size needed or the difficulty to obtain good crystals, and intrinsic properties of biomolecules such as large molecular weights and high flexibility. In this context, computational prediction of three-dimensional structures has lately become a readily applicable approach to generate structural data when no further evidence is available. Enough computational power is now accessible and affordable, and modern methods, although still far from perfect, can provide sufficiently reliable and useful structure models.

Several methods exist that can predict one or more likely conformations of the target molecule that might resemble its native conformers. Historically, the most successful methods have been those that try to derive three-dimensional information from close homologues of known structure. This comparative modeling approach is better suited for globular proteins of identifiable folds, where a suitable template should be easy to retrieve. When no homologous structure is available, or when trying to reconstruct

hard targets such as membrane proteins or intrinsically disordered regions, template-free methods can derive hundreds or thousands of structures from first principles, aiming to include a sample of several native-like conformations among them. Similarly, RNA structure prediction can be performed *ab initio* or based on secondary structure elements and long-range tertiary contacts (Laing and Schlick, 2011). RNA molecules can be represented as highly simplified, coarse-grained models that work better for long RNAs, or detailed all-atom simulations most suitable for small RNAs (Laing and Schlick, 2010, 2011). Overall, nevertheless, modeling of RNA tertiary structure still suffers from our relatively limited knowledge of RNA native structures.

The struggle for better structural modeling techniques led to the establishment of several efforts for the large-scale evaluation of protein structure prediction methods. Although now deprecated, LiveBench (Bujnicki *et al.*, 2001) and EVA (Eyrich *et al.*, 2001; Koh *et al.*, 2003) were the first to offer an automated benchmark of several public methods. The Critical Assessment of protein Structure Prediction (CASP) experiments (Moult *et al.*, 2017) are the longest-running and quite possibly most productive of these initiatives. Every two years since 1994 (Moult *et al.*, 1995), the organizers of CASP propose several target proteins which structures remain unknown to the participants but have already been solved experimentally by external collaborators. Developers of manual and automatic programs for protein structure modeling submit their predictions on these targets, for the assessment of the structural similarity between target and model structures and the overall quality of the prediction methods employed. The last published results continue to show a steady progress in modeling performance, with yet much room for improvement (Moult *et al.*, 2016). Although template-free modeling techniques (for the rare cases where no structure with detectable similarity to the target is available) has proven to successfully predict large proteins (Ovchinnikov *et al.*, 2016), this area remains particularly challenging (Kinch *et al.*, 2016). Thus, CASP ROLL (Moult *et al.*, 2014) has been introduced to provide a continuous and equally blind assessment of *de novo* structure prediction. Similarly, and recognizing the constant need for better quality assessment methods, the Continuous Automated Model EvaluatiOn (CAMEO) (Haas *et al.*, 2013) provides an ongoing evaluation of protein structure prediction servers by comparison to novel experimental structures released by the PDB (Berman *et al.*, 2000). A similar effort has been set up more recently by the RNA structure modeling community. Named RNA-Puzzles (Cruz *et al.*, 2012), it provides a blind evaluation of prediction methods on a wide diversity of functional RNA molecules, including large RNA structures (Miao *et al.*, 2015), riboswitches and more (Miao *et al.*, 2017).

This article discusses the Model Quality Assessment Programs, or MQAPs for short, which aim to predict the quality of three-dimensional structure models of biomolecules by applying computational methods that produce global and/or local scores. The field of Model Quality Assessment (MQA) was introduced as a CASP category in CASP7 (2007) (Cozzetto *et al.*, 2007), when participants were assessed on their ability to determine a priori the quality of models built by prediction servers for CASP targets. Since 'quality' is hard to define, and thus cannot be assessed confidently, Estimation of Model Accuracy (EMA) was recently proposed as a more descriptive definition of the task (Kryshtafovych *et al.*, 2016). Although this is a fair concern, the terms MQA and MQAP have been extensively used in the community and are preferred for this work.

Many programs allow scoring and ranking of structural models, or decoys, based on their intrinsic properties and regardless of the availability of an observed structure. Several other protocols can be used for benchmarking models by comparing them to known experimental structures. Some programs propose a mixed approach that relies on the comparison of the model under evaluation with a set of alternative decoys, built for the occasion, to identify conserved structural features. Although these approaches can be collectively referred to as MQAPs, they serve different goals and thus will be treated as separate categories. This article tries to avoid outdated and conflicting resources. For example, different energy functions have been used as single scores for the determination of the top-ranked models and may qualify (perhaps incorrectly) as MQAPs, but they are not covered extensively here. This article is also not intended as a comprehensive catalogue of all available methods for structure quality assessment. Instead, it recalls those methods which have had an impact on the field and highlights other established alternatives that are part of the current state-of-the-art. Also, it is not focused on the algorithms and parameters of the methods, but rather presents their foundations and comments on their applicability.

Background/Fundamentals

The biomolecular modeling community has reached a point of maturity in which the generation of structural models appears straightforward. However, their quality would be largely dependent on the properties of the target molecule, the capabilities of the program employed and the knowledge and experience of the researcher for selecting the right tools and options. Given this complexity, it is hard to ensure in advance the adequacy and utility of models that are generally derived from approximate methods. Most programs rely on finding the most efficient paths towards native-like models, even if these are not optimal. To cope with this limitation, a usual choice is to output a varying number of possible models, expecting that they will provide enough good options. Therefore, regardless of the modeling procedure, a crucial step is the ability to score, rank and select among the many models proposed (Kihara *et al.*, 2009). This is generally attempted by a large-scale computational assessment of structure quality, possibly followed by human evaluation of outstanding candidates. Both protein and RNA structures can be assessed in relationship to a reference structure or by analysing their characteristic structural features. Proteins are organized hierarchically, from local geometric arrangements and bonding patterns that define secondary structures, drive the adoption of conserved tertiary folds and favour interchain contacts to form functional complexes. RNAs are defined by specific base pairing and stacking patterns which result in local structure motifs like bulges, stems or hairpin loops, linked by long-range interactions that determine the tertiary structure. These features, like many others, can be extracted from high-confidence existing structures and processed in different ways to generate a knowledge-based predictor of model quality.

Energy functions have been used for a relative estimation of model accuracy since the first attempts in structural modeling. Early studies on incorrectly folded protein models demonstrated that wrong models can have comparable energy values to acceptable structures, even if their interactions, side-chain packing, or solvent accessibility are distorted (Novotný *et al.*, 1984, 1988). Further developments led to more comprehensive and specific formulations to estimate the total free energy of structural models. For example, MODELLER (Sali and Blundell, 1993) applies internal scoring functions to assess its protein homology models, including the empirical and distant-dependent Discrete Optimized Protein Energy statistical potential (DOPE) (Shen and Sali, 2006). The ROSETTA suite for ab initio structure modeling (Leaver-Fay *et al.*, 2011) combines a statistical potential with a physical energy function for the scoring of ab initio protein and RNA models. Unfortunately, energy-based scores such as these are limited in their approach. Given the enormous diversity and changing nature of biomolecules, it is difficult to determine empirically and model reliably the expected energy of each native structure. An evaluation based in energy properties may oversee other conflicting characteristics of the models; plus, it would not be possible to draw a line between good and bad predictions based on their energies alone. With programs applying different definitions and optimizations of the energy calculation, their scores may not be directly comparable among structures. Therefore, they could only be used for relative rankings of models obtained by individual programs, which may generally not converge to the same answer. To deal with these issues, a whole set of criteria for testing the quality of structure models have matured over the last decades, implemented through many programs specifically designed for the task.

A common approach to determine the quality of structure models has been the evaluation of their stereochemical properties. Both PROCHECK (Laskowski *et al.*, 1993) and WHATCHECK (Hoofit *et al.*, 1996) quantify the deviation in several structural measures between the models and known protein structures. These methods oversee that both native and non-native models can be stereochemically correct. To differentiate among these, several programs incorporate energy functions or statistical potentials derived from the analysis of known structures. Two highly popular approaches have been PROSA II (Sippl, 1993), with a knowledge-based energy function built from inter-residue distance probabilities, and VERIFY3D (Eisenberg *et al.*, 1997), which evaluates the compatibility of the primary and tertiary structures of a model according to a 3D profile of the structural environments observed in real structures. All the previous methods have enjoyed the greatest relevance in the first years of model quality assessment, and although other approaches have proved to be more effective (many of them covered in Section “Model Quality Assessment of Protein Structures”), usage of these methods can still be found in new publications.

Model quality assessment programs can be organized into different categories depending on their general approach to model evaluation. Single-model programs estimate global accuracy by assigning an absolute score to each model based on their geometrical or energetic properties alone. Their performance would depend on a good correlation of the scoring function with actual model quality. Global consensus-based methods (also called clustering methods), while may still calculate absolute scores, would also aim at providing a reliable ranking of a set of models by performing all-against-all comparisons, recognizing the best one(s) and ideally drawing a line between good and bad structures. A mixed type are the quasi-single-model MQAPs. These methods take as input a single model and expands it into an extensive set of decoys, which could be built *ad hoc* with local or external methods. They assess the quality of every model by pairwise comparisons against a subset of high-quality models, taken as reference from the dataset via single-model methods. A special category could be the meta-methods, which combine predictions from different MQAPs into a single quality score. It can be argued that these methods are single-model or consensus-based approaches depending on the nature of the scores they combine; thus, for simplicity, meta-methods are not treated separately in this manuscript. The methods described above may evaluate model accuracy at different levels. Local predictors would seek a per-residue evaluation, while others would provide a unique descriptor of the global quality of the model, either by combining local scores or by analysing the structure as a whole. Also, they can be implemented as automatic, semi-automatic or manual methods, requiring varying levels of human intervention to run the programs and translate raw evaluation results into meaningful information.

Applications

The following subsections present a selection of current relevant options for model quality assessment. The information is organized for protein and RNA structures separately, although some methods can be applied to both types of macromolecules. MQAPs are also classified based on their general approach to assessment, with methods measuring similarity to a reference structure, predicting the quality of single models alone, or by a consensus analysis of multiple decoys. A summary of the classification, characteristics and online availability of these methods is provided in Table 1.

Model Quality Assessment of Protein Structures

Validation against reference structure

Programs to calculate root mean square deviation (RMSD)

RMSD (Nishikawa and Ooi, 1972; Levitt, 1976) is a measure of the average Euclidean distance between equivalent atoms of two biomolecular structures, computed as

$$RMSD = \sqrt{\frac{1}{N} \sum_{i=1}^N d_i^2}$$

where d_i is the Euclidean distance between the i -th pair of atoms, one from each structure, and N is the total number of pairs being considered. RMSD is expressed in units of length, with Ångström (Å, equal to 10^{-10} m) being the most common. Calculation of RMSD requires a good (and fast) or optimal superposition of the structures to minimize the distances (Kabsch, 1976; Coutsias *et al.*, 2004).

RMSD is a simple and yet useful measure that has been so widely adopted for the last three decades that it is pointless trying to enumerate all implementations available. It is currently possible to calculate RMSD using standalone tools (such as MAMMOTH (Ortiz *et al.*, 2002)), web servers (e.g., SuperPose (Maiti *et al.*, 2004)) and bioinformatics software libraries (including BioPython (Cock *et al.*, 2009), BioJava (Holland *et al.*, 2008) and other extensions to popular programming languages). Although RMSD has been widely applied as a measure of global similarity, programs such as ProFit, which implements a special least squares fitting algorithm (McLachlan, 1982), provide local RMSD values to compare specific regions or even individual residues. Some programs, like TopMatch (Sippl and Wiederstein, 2012), would not limit the comparison to RMSD values but extend the output with additional descriptors of structural similarity. Each program may introduce small variations to the calculation to suit different goals. For example, RMSD is often computed from distances between C α atoms only, but C β and other sidechain carbons can also be incorporated. RMSD relies on a superposition of the structures that could treat them as rigid bodies, as in the Combinatorial Extension (CE) algorithm (Shindyalov and Bourne, 1998) or allow some flexibility for more accurate alignments (e.g., in FatCat (Ye and Godzik, 2004)).

Levitt-Gerstein score (LG-score)

LG-score (Levitt and Gerstein, 1998) was designed to tolerate local fluctuations in order to gain sensitivity for the similarity in global topology. It was first developed as a standalone application but, since the early 2000s, it has been adopted and modified for the development of several other similarity measures, as exposed in the following sections.

Superposition of two structures is performed by first calculating all pairwise distances between every atom in each structure, which are then used for an iterative process of least-squares fitting of one structure onto the other. Prioritization of global similarities is achieved by setting an empirically derived distance cutoff (typically 5 Å) to downweigh equivalent residues far from each other, such as those that can be found in flexible local regions. This is directly incorporated into the original LG-score formulation:

$$LG = M \left(\sum \frac{1}{1 + (d_{ij}/d_0)^2} - \frac{N_{gap}}{2} \right)$$

Here $M=20$, d_{ij} is the distance between equivalent residues i and j (the summation is performed over all pairs), d_0 is the distance cutoff (5 Å) and N_{gap} is the total number of internal gaps in the alignment. Thus, the LG-score represents the score of the best alignment found by the algorithm. The LG-score can be transformed into a statistical significance score or P-value, independent of protein size, by comparison to a distribution of scores from random alignments of unrelated proteins.

MaxSub

MaxSub (Siew *et al.*, 2000) identifies the largest subset of C α atoms of a protein structure model that can be superposed correctly on the equivalent atoms of a reference structure. Given the complexity of the process, the maximal superposition needs to be found by an heuristical algorithm. MaxSub uses a sliding window of a certain size (usually 4 residues) to compare equivalent residues in an initial residue-based alignment. In each comparison step, the algorithm adds the residues that are within a distance threshold of each other (3.5 Å by default) to the largest subset found so far, recalculating the superposition of this set and removing those residues that exceed the threshold afterwards. When the algorithm converges to a global alignment, a single, normalized score S is calculated as:

$$S = \left(\sum_i^N \frac{1}{1 + \left(\frac{d_i}{d}\right)^2} \right) / q$$

Here d_i is the distance between the i -th equivalent C α atoms and d is the distance threshold for the comparison; the sum is performed over all residues i in the largest aligned subset and normalized by q , the number of C α in the reference structure. The MaxSub S score ranges from 0 when no superimposable atoms are found to 1 when the structures are identical.

Template Modeling score (TM-score)

TM-score (Zhang and Skolnick, 2004) was designed as a size-independent, normalized and alignment-based variation of the LG-score. After optimal superposition of the model and reference structures, the TM-score is calculated almost identically to the MaxSub S score, but with the threshold d replaced by a d_0 scale factor. Therefore, the distances between all residues aligned to the reference structure are considered (instead of only those with $d_i < d$ as in MaxSub), giving stronger weights to close contacts. TM-scores are within the range (0,1] with higher scores indicating more similarity. It was found empirically that TM-scores < 0.20 correspond to random alignments, while TM-scores > 0.50 indicate a conserved fold.

Local-Global alignment (LGA)

LGA (Zemla, 2003) was designed to provide the best global superposition between two structures while simultaneously finding their regions of local similarity, either with or without the use of an alignment to define equivalent residues. LGA applies

two complementary algorithms, LCS and GDT (see below), to identify continuous segments of superimposable residues and to provide the largest superimposable sets of residues, respectively. Their similarity scores are linearly combined in the scoring function LGA_S, which allows selection and ranking of similar regions and helps in evaluating the total level of structural similarity.

Longest continuous segments (LCS)

LCS Identifies the longest fragment of connected residues within the predicted model for which the RMSD against the target is below certain thresholds (1 Å, 2 Å and 5 Å are generally selected). The use of several RMSD cutoffs allows detailed inspection of local similarities that may go unnoticed under a unique value.

Global distance test (GDT)

Given two structures, GDT finds the largest set of residues in common that fit under a predefined distance threshold. Since the residues do not need to be connected to each other, this is a measure of whole structure similarity. The algorithm starts by obtaining the RMSD and a superposition of all continuous segments identified by LCS, plus all possible segments of three, five or seven residues. Then, it iteratively extends the list of equivalent residues by adding all those that fit under the chosen thresholds. Typical values are in the range of 0.5–10.0 Å, with a step of 0.5 Å. Many variants of the GDT score can be applied. To provide a single-value description of structural similarity, the Global Distance Test Total Score (GDT_TS) (Cristobal *et al.*, 2001) was defined as the average of GDT calculations at 1 Å, 2 Å, 4 Å and 8 Å cutoffs:

$$GDT_{TS} = (GDT_{1\text{\AA}} + GDT_{2\text{\AA}} + GDT_{4\text{\AA}} + GDT_{8\text{\AA}}) / 4\text{\AA}$$

Therefore, GDT_TS represents the average coverage of the reference structure by all common substructures. It has become the *de facto* version of GDT, although a stricter High Accuracy variant (GDT_HA), where the cutoffs are reduced in half, is also frequently observed. It also provides a standard of quality in CASP, where the correlation to the GDT_TS has been used to evaluate model quality assessment methods.

Dali

Dali (Holm and Laakso, 2016) has been a reference method for protein structure comparison for the last two decades (Holm and Sander, 1993). The program and its web server version search for the largest common substructure between two structures (e.g., a model and a reference conformation) to calculate a suboptimal alignment. This is built by comparing the distance matrices of all-versus-all C α contacts in each structure, building up from elementary patterns such as hexapeptides. The significance of the structural similarity between two structures *A* and *B* is measured by a unique quantity, called Z-score, defined as

$$Z = \frac{S(A,B) - \mu(N)}{\sigma(N)}$$

Here, $S(A,B)$ is the sum over all pairs of residues in the common substructure of *A* and *B*, of a custom pairwise similarity score that accounts for the distance between residues (see Supplementary material in Holm and Rosenström (2010) for more details). $\mu(N)$ and $\sigma(N)$ represent the mean and standard deviation of the *S* scores, respectively, averaged for different protein lengths. A structural alignment is considered significantly different from a random alignment when $Z > 2$. Therefore, the Z-score represents a relative measure of structural similarity that, while not directly useful to compare unrelated structures, can be taken as a quantitative indicator of the ‘native-likeness’ of a protein model with respect to a native structure.

local distance difference test (lDDT)

lDDT (Mariani *et al.*, 2013) provides a score of local distance differences between a model and one (or many) reference structures, without the need of superposing the structures in advance. To achieve this, lDDT calculates all pairwise interatomic distances between residues that are found below a certain threshold in each structure. The final lDDT score is the average fraction of conserved interatomic distances at thresholds 0.5 Å, 1 Å, 2 Å and 4 Å. Since the distances are evaluated per atom, both local (residue-based) and global scores can be determined.

CAD-score

CAD-score (Olechnovič *et al.*, 2013) evaluates atomic-level contact area differences (CAD) in physical contacts between a model and a reference structure of a macromolecule, including proteins and nucleic acids. Each of the contact areas, modelled from a Voronoi tessellation of the structure, contain a C α and all points of the protein surface closer to this than to any other C α . The analysis can comprise the whole structure or just an interface. Both local and global scores are provided and allow all pairwise comparisons between all-atom contacts, contacts of atoms in side chains or contacts involving main chain atoms only.

Single-model and quasi-single-model MQAP

MolProbity

MolProbity (Davis *et al.*, 2004) is a web-server and standalone suite of programs for local and global validation of both protein and nucleic acid structures. Its signature feature is the calculation of the number of steric clashes, defined by overlaps ≥ 0.4 Å, and its proportion per thousand residues (the “clash score”) (Word *et al.*, 1999). It can be used to identify weak or missing hydrogen

bonds where expected, unusual van der Waals contacts leading to under- or over-packing and deviations of covalent bond lengths and angles in any 3D structure. It provides additional protein-specific validations like Ramachandran analysis, assessment of peptide bond angles and cis-peptides and identification of unexpected beta-carbon geometries and side-chain rotamers. Some of these scores have been incorporated into the Structure Validation Reports, available for the structures deposited at the worldwide Protein Data Bank websites (Read *et al.*, 2011).

ProQ

ProQ (Wallner and Elofsson, 2003) and several of its variants have been among the top performers in many of the CASP competitions. The original method introduced the ability to predict the quality of a protein structure model, aiming to separate correct models among many incorrect alternatives. ProQ trains a neural network to estimate the values of typical structural similarity measures that would be achieved by a protein model if it were compared with a reference structure. In particular, ProQ informs the expected values of the LG-score and the MaxSub score. Training is based on several structural features that can be calculated from any single protein structure, both at local level (interatomic and residue contacts) and more globally (solvent accessibility, secondary structure, overall shape). Although ProQ provides a global quality score, it was later extended for local prediction with the ProQres method (Wallner and Elofsson, 2006).

ProQ2 (Ray *et al.*, 2012) is based on the same ideas of ProQ, but successfully improved to be the top performing method in different benchmarks (Uziela and Wallner, 2016). In ProQ2, an update and extension of sequence and structure features was combined with individual weighting of all residues based on evolutionary profiles obtained from sequence alignments. This enables a local prediction of quality represented by the S-score, originally by Levitt and Gerstein, but calculated here for each residue i with a distance cutoff $d_i=3 \text{ \AA}$, as follows:

$$S_i = \frac{1}{1 + (d_i/d_0)^2}$$

The local scores for all residues are averaged to yield a global quality measure of correctness in the range [0,1].

The latest versions of ProQ achieve a better assessment of model quality by incorporating methods of machine learning based on deep learning from input parameters. Different approaches have been developed, with ProQ3 (Uziela *et al.*, 2016) using Support Vector Machines (SVMs) and ProQ3D (Uziela *et al.*, 2017) applying a deep neural network. Both ProQ3 and ProQ3D combine the input features used in ProQ2 with two energy potentials taken from the Rosetta ab initio modeling suite (Leaver-Fay *et al.*, 2011): one potential is based on all atoms for greater accuracy, while the other only considers simplified side-chain representations to account for incomplete models.

MESHI-Score

MESHI-Score (Mirzaei *et al.*, 2016) is a machine learning method that aims to predict the real GDT_TS score of a protein model, based on the combination of estimates of numerous structural features made by an extensive number of predictors. ~80,000 decoys from the latest CASP experiments were used to train more than a thousand prediction functions. Each predictor was trained on a non-linear combination of 15 features selected at random from pairwise energy potentials, bond lengths and angles, solvation, radius of gyration, protein frustration, compatibility of predicted and observed secondary structure and solvent accessibility, etc. To predict the quality of a decoy, it is first regularized to correct structure or energy inconsistencies, and their structural features are then fed to the predictors for determination of the individual scores. The weighted median of these scores constitute the MESHI-Score global assessment of quality.

SVMQA

SVMQA (Manavalan and Lee, 2017) is a single-model global quality assessment program based on support vector machines. These have been trained on target domain from previous CASP experiments to predict TM-score and GDT_TS. The prediction is performed through a combination of 8 statistical potential energy terms and an estimation of the compatibility between 11 structural features predicted from sequence and observed in the model. If a set of alternative models is provided, SVMQA can both rank the models and select the best from a given subset.

ModFOLD

ModFOLD (McGuffin, 2007) was originally developed as a single-model quality assessment method. The evaluation was performed with an artificial neural network trained to predict TM-score as a measure of quality, using a combination of outputs from ProQ, the ModCHECK method for assessing sequence-structure compatibility using threading potentials (Pettitt *et al.*, 2005) and the ModSSEA method based on the alignment of secondary structure elements that were predicted in the target and observed in the model (McGuffin, 2007). After further improvements (McGuffin, 2009), ModFOLD3 (Roche *et al.*, 2014) pioneered the development of quasi-single MQAPs for local and global validation, using ModFOLDclust2 to compare the structure of interest with alternative models generated ad hoc. The ModFOLD3 web server has been consistently ranked among the top methods for quality assessment in recent CASP editions (Kryshtafovych *et al.*, 2014; Kryshtafovych *et al.*, 2016).

ModFOLD6 (Maghrabi and McGuffin, 2017) is the latest version of the method. Although it now works under a hybrid approach, it is still among the best performers in CASP. The neural network is now trained and applied with scores from three single-model methods (ProQ2 and the newly developed Secondary Structure Agreement, SSA, and Contact Distance Agreement,

CDA) plus three quasi-single model scoring methods (Disorder B-factor Agreement, DBA, and residue-specific versions of the ModFOLD5 and ModFOLDclust algorithms). For each model, the output is a set of improved per-residue quality scores, together with their mean value as an indicator of global quality. Two variants of ModFOLD6 were presented that differ in the criterium used for global model ranking. ModFOLD6_rank (the default option in the ModFOLD web server) optimizes the selection of models with best quality, even if their predicted scores do not resemble the observed. Instead, ModFOLD6_cor optimizes the correlation between predicted and observed global scores.

Qualitative model energy analysis (QMEAN)

The QMEAN scoring function (Benkert *et al.*, 2008) is used to derive local and global quality assessments for single structure models. It is formulated as a linear combination of four statistical potentials covering the local geometry and interactions within the model, with two terms describing the agreement of predicted and observed secondary structure and solvent accessibility. The global scores are expressed in the range [0,1] (with higher scores for better models). However, the QMEAN web server transforms them into statistically valid Z-scores by comparison with the expectations from a dataset of high-resolution X-ray crystallography structures. Local scores are color-coded within the same range and mapped onto each position of the sequence.

The hybrid version QMEANclust (Benkert *et al.*, 2009) allowed the evaluation of an ensemble of alternative models via an all-against-all comparison of single-model QMEAN scores. QMEANclust calculates QMEAN scores of all models to identify the subset of highest-scoring candidates. Their pairwise distances are calculated as GDT_TS scores and then converted to global QMEANclust scores (the median of a model's GDT_TS to all others). The best models are taken again for the calculation of local consensus scores, but as the selection is now based on their QMEANclust scores, this increases the probability of analysing locally correct conformations.

Qprob/MULTICOM-NOVEL

Qprob (Cao *et al.*, 2016a) is a novel method for quality assessment based on a statistical analysis of estimated errors in the prediction of model structure features. Besides being a standalone tool, Qprob is part of the MULTICOM suite, thus sometimes referred to as MULTICOM-NOVEL (Cao and Cheng, 2016). For each model, Qprob calculates the scores for several descriptors of secondary structure, compactness and solvent accessibility and four different energy scores, all normalized in the range [0,1] when needed. Each of these feature scores is compared with a probability density function (p.d.f.) to predict a feature-exclusive global quality score. This p.d.f. needs to be calculated from a reference set of structures. Here, the same features were extracted from many CASP9 decoy sets and contrasted with the real GDT_TS score against the target structure. Assuming a normal distribution of the differences between predicted and observed scores, their mean and standard deviation are obtained and used for the calculation of the p.d.f. Finally, a weighted combination of the predicted scores for all 11 features provides a single score taken as global estimator of model quality.

A mixed approach (Cao *et al.*, 2014a) was also designed to improve the selection of good models by identifying them with a comprehensive selection of quality assessment methods, combined with a clustering procedure to ensure diversity among the selected models. Decoys were scored by combining 14 single-model quality assessment methods such as ProQ2 and Qprob/MULTICOM-NOVEL, plus clustering methods like Pcons and ModFOLDclust. The average scores from all MQAPs and from six selected methods are used together with a clustering procedure to select the top five and sufficiently diverse models.

MetaMQAP

MetaMQAP (Pawlowski *et al.*, 2008) is a meta-server that predicts the local and global structural deviation of a model against the real (and possibly unknown) structure. It uses a machine learning approach, based on a multivariate linear regression model originally trained on CASP5 and CASP6 datasets, to combine the output of several MQAPs and local structure descriptors. The regression model is applied on selected residues to avoid prediction biases from trivial features like accessibility, hydrophobicity, secondary structure, etc. MetaMQAPII, the latest version of this program, reports a score that predicts the absolute deviation of each C α atom against the equivalent atom in the putative reference structure.

VoroMQA

VoroMQA (Olechnovič and Venclovas, 2017) is an all-atom statistical potential-based MQAP built on the same principles than the CAD-score, but without the need for a reference structure. Observed interactions within the protein and inferred contacts with solvent atoms are described by contact areas instead of the commonly used atom distances. VoroMQA provides a normalized score at the atomic, residue and global levels.

Consensus MQAP

Pcons

Pcons (Lundström *et al.*, 2001; Wallner and Elofsson, 2007) was the first automated consensus method in CASP. Given a structure of interest, a set of alternative models is obtained from several public servers for fold recognition. Models from different servers are collectively compared to identify common structural patterns which would be more likely to be correct. In this regard, it is similar to the once popular but now discontinued 3D-Jury method (Ginalski *et al.*, 2003), but the structural superposition is performed in Pcons using the Levitt-Gerstén algorithm. The models are ranked using a neural network approach that predicts the residue-based S-score of model quality and its global average, as in Section ProQ.

ModFOLDclust

When many models of a target protein are available, ideally built with several alternative modeling methods, ModFOLDclust (McGuffin and Roche, 2010) would probably offer the most accurate local and global quality assessment results among all the ModFOLD-derived methods. The original ModFOLDclust algorithm adapted the 3D-Jury method (Ginalski *et al.*, 2003), just like Pcons, and later incorporated per-residue quality scores. ModFOLDclust2 is the faster and still accurate current version of the method. It combines (by averaging) the scores from ModFOLDclust with the scores provided by ModFOLDclustQ, a variant that uses the Q estimate of structural similarity based on internal residue distances (McGuffin and Roche, 2010). The high speed of the latter algorithm allows clustering of many thousands of alternative models without compromising accuracy. It is now developed as part of ModFOLD.

Pcomb

Pcomb (Larsson *et al.*, 2009) (called Wallner in CASP11) is a consensus approach for local and global quality assessment. The Pcomb score is derived from a linear combination of the scores from a single-model ProQ method (originally ProQ2, now using ProQ3) and the consensus-based predictor (ProQ and Pcons, respectively), optimized with a four-fold higher weight to the former. Pcomb-domain (Elofsson *et al.*, 2017), a slightly modified version that uses an initial definition of domains, was also developed to identify good models of individual domains that are not among the best for the whole structure.

Model Quality Assessment of RNA Structures***Validation against reference structure****Programs to calculate RMSD and other traditional measures in proteins*

Like in protein quality assessment, RNA structure models can be evaluated by comparison to a reference structure taken as gold standard of native-likeness. Structural distance is usually determined by typical scores for protein comparisons, most commonly Root Mean Square Deviation (RMSD), TM-score, GDT_TS and CAD-score. However, as presented in the following subsections, new programs and scoring functions were developed that not only calculate these measures, but also account for RNA-specific features like base pairing constraints. Many model-reference comparisons are alignment-based, and some programs, besides identifying equivalent residues, provide different similarity measures that help to assess the quality of the predicted models (see for example Rclick).

iFoldRNA

Besides its main goal of providing RNA folding simulations, the iFoldRNA web server (Hajdin *et al.*, 2010) can be used to estimate the statistical significance of an RMSD value. This is achieved by computing the RMSD *P*-value against a pre-calculated distribution of RMSDs obtained from conformational space sampling of RNA molecules using replica-exchange discrete molecular dynamics. These RMSD are normally distributed, with a mean dependent on the length of the molecule and whether base pairing constraints were considered or not. *P*-values > 0.01 can be taken as successful predictions in which RNA models are better than those expected by chance.

RNAlyzer

RNAlyzer (Lukasiak *et al.*, 2013) is a standalone application that facilitates a quantitative and visual evaluation of RNA structure models by contrast to a reference structure. For every nucleotide of the reference structure, the program defines the set of atoms in the whole structure that are located inside a sphere of a certain radius and centered on a user-selected atom (either P, C1', O5' or O3'). These are superposed with their equivalent atoms from the model and the RMSD between them is determined. The comparison can be based on all atoms or restricted to a selected type.

RNAlyzer uses increasing sphere radii to simultaneously plot the structural distance between multiple models and the reference structure at different accuracy levels, thus describing the change in prediction quality from local environments to the whole structure. Multiple-model plots allow visual ranking of the predicted models, while detailed individual representations are available for nucleotide-specific inspection of prediction quality. RNAlyzer remains one of the few methods for local evaluation of RNA structure models.

RNAssess

RNAssess (Lukasiak *et al.*, 2015) is a web server built on the RNAlyzer framework by the same authors, adding the convenience of an online resource. Like RNAlyzer, it provides a continuous comparison of predicted and known structures from local to global environments, with multi-model and single-model plots available for a detailed quality assessment. A defining feature of RNAssess is that several metrics can be applied for a tailored comparison against the reference structure. In particular, it provides direct access to Deformation Index and Deformation Profile, two useful similarity metrics designed specifically for RNA structures that have been adopted for the official ranking of models submitted to RNA-Puzzles (Miao *et al.*, 2017).

Deformation index (DI)

The Deformation Index (Parisien *et al.*, 2009) is a normalization of the RMSD by the base Interaction Network Fidelity (INF), which accounts for the accuracy in predicted base-pair and base-stacking interactions:

$$DI = \frac{RMSD}{INF}$$

The complete sets of interactions between nucleotides in each of the structures are compared by set theory operations to build a confusion matrix of True and False predictions. This is used to compute INF as the Matthews Correlation Coefficient (MCC), a measure of quality for binary classifications that equals 1 when the model reproduces the exact base interactions found in the reference (and consequently, $DI = \text{RMSD}$) and approaches 0 (with DI tending to infinite) as the number of shared interactions diminishes.

Deformation profile (DP)

The Deformation Profile (Parisien *et al.*, 2009) consists of a distance matrix of size $N \times M$, where N and M are the lengths of the model and reference structures, respectively. Taken in turns, each pair of equivalent nucleotides is optimally superposed, affecting the relative positioning of all other nucleotides. In each step, the average distances between all corresponding nucleotides are calculated. The resulting RMSD values are stored as one row of the matrix; its average value would be indicative of local similarity around the nucleotide. Similarly, average values of each column would suggest if the distance between the pair of nucleotides is highly dependent on the prediction quality of all other nucleotides. The main diagonal stores the average atomic distance of each nucleotide. Defined this way, DP values can simultaneously suggest similarity at different scales, with the global DP score simply computed as the average distance between a model and the reference structure.

Mean of circular quantities (MCQ4Structures)

MCQ4Structures (Zok *et al.*, 2014) implements the Mean of Circular Quantities (MCQ) algorithm. It was designed to assess similarity based on a reduced trigonometric depiction of RNA structure where every nucleotide is only represented by eight torsion angles. MCQ shows the dissimilarity between two RNA structures, computed from the distances between each pair of equivalent torsion angles (see extended definition and formula in Zok *et al.* (2014)). Thus, MCQ is a distance measure, with greater MCQ values showing more structural differences.

Longest Continuous Segments in Torsion Angle space (LCS-TA) (Wiedemann *et al.*, 2017) is an extension of the MCQ algorithm that allows identification of the longest contiguous segment with significant local similarity between two structures. For any pair of segments compared, a certain MCQ maximum threshold should be defined by the user to address if their sets of torsion angles are similar. LCS-TA informs the MCQ score of the longest segment under this threshold, its location within both structures and its length (called LCS) serving as a measure of local similarity. LCS-TA has been implemented as part of the MCQ4 Structures application by the same group.

Rclick

Rclick (Nguyen and Verma, 2015; Nguyen *et al.*, 2017) extends the CLICK algorithm (Nguyen *et al.*, 2011; Nguyen and Madhusudhan, 2011), designed for optimal protein structure superposition, to the alignment of pairs of RNA structures. It can be used to provide a set of alignment-based statistics representing the RNA model-reference structural similarity. Rclick reduces the structures to sets of three to seven nucleotide residues, each represented by one or more points in space, and in which all possible interconnections are considered. These sets, or cliques (a term borrowed from graph theory), are subjected to a least squares fit to identify and superpose equivalent residues between the structures. Since the connectivity between residues is not relevant for clique matching, Rclick works as a topology-independent alignment program. The output of the Rclick server informs the RMSD and structure overlap (number of equivalent positions within 4 Å) between the optimally aligned structures. These are common structural similarity measures that are also presented by other RNA structure alignment tools such as SETTER (Cech *et al.*, 2012). More importantly, Rclick calculates a Fragment Score, which becomes maximum when all equivalent fragments are contiguous in both sequences, plus a Topology Score that is maximized when the matched fragments have the same directionality.

Single-model and Quasi-single-model MQAP

MolProbity

MolProbity (Davis *et al.*, 2007) provides several automatic analyses of local and global quality for different types of biological structures. It was already covered before for the assessment of protein structure models. Besides general assessments for both proteins and nucleic acids, evaluation of backbone conformations and incorrectly modelled ribose sugar puckers is also available for single RNA structures.

Consensus MQAP

Fragment assembly of RNA with full-atom refinement (FARFAR)

FARFAR (Das *et al.*, 2010) is an extension of the original FARNAL protocol (Das and Baker, 2007) based on the Rosetta methodology for ab initio modeling (Leaver-Fay *et al.*, 2011). It includes a novel and more descriptive force field which allows prediction and assessment of RNA 3D models of multiple sizes, from small motifs to complex folds. FARFAR, like many others, generates sets of decoys that can be clustered according to fold similarity to select groups of native-like models. A clustering procedure was developed to select the largest cluster of lowest-energy structures with less structural divergence among them (Cheng *et al.*, 2015). By setting an appropriate RMSD threshold within each cluster it is possible to control the allowed variability of the modeling procedure and thus estimate its predictive accuracy.

WebRASP

WebRASP (Norambuena *et al.*, 2013) is an online implementation of the standalone Ribonucleic Acids Statistical Potential (RASP), a knowledge-based, distance-dependent pairwise contact potential for RNA structures (Capriotti *et al.*, 2011). The

WebRASP server calculates the total energy score, the normalized energy per contact and the energy profile per site for a single RNA structure. Its output allows visual mapping of energy scores, coded by color gradients, onto the RNA structure. Since the energy scores do not have a direct correlation with prediction quality, it works as a consensus-based MQAP in which all models under scrutiny should be run and later ranked manually for a comparative determination of the best predictions.

3dRNAScore

3dRNAScore (Wang *et al.*, 2015) is an empirical potential for RNA structure evaluation. Its contact potential adds the contribution of RNA base-stacking between adjacent nucleotide residues to total energy calculations. Moreover, it also contemplates the stability effect of backbone torsion dihedral angles, which are directly related with RNA structure flexibility.

The latest version of the 3dRNA web server (Wang *et al.*, 2017) implements 3dRNAScore for a consensus assessment and ranking of its own predicted RNA models. The models are built from their secondary structure elements, selecting from a template library of helices and loop conformations which are later assembled into a complete tertiary structure. Further refinement by simulated annealing is performed, including the use of co-evolutionary information by Direct Coupling Analysis (DCA) (Morcos *et al.*, 2011; Weinreb *et al.*, 2016) to contemplate direct interactions between nucleotides. The final models are clustered by the density-based DBSCAN method (Ester *et al.*, 1996) that groups close structures together. 3dRNAScan is applied to all models in the five most populated clusters to select the best model from each of them.

Analysis and Assessment

Validation against Reference Structure

RMSD has been commonly used to quantify dissimilarity between two or more biomolecular structures, and therefore, it also became a method of choice for validation of protein and RNA models when the reference structure is known. Despite its simplicity and convenience, it is hardly the best option, with many known flaws such as the dependence on protein length and structure resolution (Carugo, 2007). Recognizing these limitations, the community has developed alternative and improved measures (which, unfortunately, still lack the wide adoption of the traditional RMSD, especially outside the community of experts in structural bioinformatics.) Among these is the RMSD₁₀₀, a normalization of the RMSD to reflect the expected value if the structures under comparison were 100 residues (Carugo and Pongor, 2001). In the last years, the more accurate GDT_TS score is becoming commonplace, being used as the default measure to quantify the performance in prediction of CASP participants since its third edition. Like many of the novel approaches, it was designed to find the most conserved substructure. LG-score was probably the first measure of structural similarity specifically proposed to overcome known drawbacks of traditional distances measures like the RMSD. It has had a great impact on the field, being incorporated with modifications into several other popular MQAPs like MaxSub and LGA. TM-score was first proposed as a method to evaluate structural templates for comparative modeling, under the premise that template correctness would be correlated with the measured quality of final full-length models. This role has been surpassed and TM-score is now a standard method to quantify global pairwise structural similarity.

These better methods are not without known flaws. Despite being the official measure in CASP for the last two decades, the uncertainty of GDT_TS calculations has only been estimated very recently (Li *et al.*, 2016). Also, although they are less biased than the RMSD, both the similarity scores GDT and MaxSub still show some dependency on protein length (Zhang and Skolnick, 2004). In fact, MaxSub is more likely to give a good score when the reference structure is short, while the LG-score would tend to be good for comparisons against long structures (Wallner and Elofsson, 2003). (These contrasting behaviours were cleverly combined in the development of the single-model method ProQ, with its different versions being among the best performers in many CASP editions.) A common limitation of all these methods is the need for a subjective distance threshold for selecting pairs of residues to compare, which are hard to justify and customize sensibly.

Many methods for comparison against a reference structure aim to identify the number of equivalent residues and the deviation between the superposed structures. These two scores are hard to optimize simultaneously. The assessment has often been done on C α differences alone, to account for conserved folds, but leaving non-C α out of the comparison overlooks differences in almost 90% of the atoms that constitute a protein model (Keedy *et al.*, 2009). It is expected that in good models, the overall fold similarity would compensate for highly flexible regions. Superposition-based scores like RMSD and GDT may not provide adequate measurements of quality for good models that are only partly correct. A unique global score would tend to average the comparison and miss atomic-level discrepancies, but at the same time, local structural differences would inflate the global dissimilarity score. Given the case of multi-domain proteins, treating the structures as rigid bodies does not allow consideration of changes in the relative orientation of domains, affecting the reliability of global scores. Flexible superpositions can overcome this limitation, but would only be able to provide good local or domain-based scores of long superposed substructures. Applying non-rigid-body scoring schemes would be a sensible option in those cases, and for that reason IDDT, CAD and SphereGrinder (Antczak *et al.*, 2015) have been incorporated as novel reference measures for evaluation of MQAPs from CASP11 (Kryshtafovich *et al.*, 2016). IDDT has also been the default measure in the CAMEO project (Haas *et al.*, 2017), since an automated and continuous quality assessment protocol should be robust under different scenarios. Besides, DALI and CE can provide an alternative to superposition by comparing intra-structure residue-residue distances.

The previous methods are based on comparisons of general properties against a reference structure. They can be tailored to evaluate similarity between pairs of structures of most biomolecules, including RNA models that are usually assessed by RMSD, GDT or CAD-score. RNA-specific methods are designed to contemplate special features of RNA structure that allow a more

meaningful discrimination, even among models showing similar RMSD to a reference structure. For example, the Deformation Index incorporates the evaluation of nucleotide residue interactions commonly observed in RNA structures. Organizers of the RNA-Puzzles experiments recognized the outstanding need to develop new criteria for the comparative assessment of RNA structure models at different levels, from local to global, while considering the structural topology, torsion angles, and bond angles and lengths (Miao *et al.*, 2017). There are methods such as RNAnalyzer that use RMSD to evaluate the global quality of structure models but also offers details on local environments. These could be of great importance for functional RNAs like riboswitches or ribozymes where an accurate modeling of binding or active sites is particularly wanted (Lukasiak *et al.*, 2013).

Single-model and quasi-single-model MQAP

In comparison with reference-based measures, there have been less alternatives for evaluating the quality of a model based on intrinsic properties of the model alone. This is still critical in the assessment of RNA structure models, where MolProbity is one of the few, if not the only available pure method for the analysis of individual structures. Although its clash score evaluation (Chen *et al.*, 2010) is widely used, it is limited to the assessment of atomic distances only. Protein-based single-model methods were also uncommon, with only 5 participants in this category in CASP10 (Kryshtafovych *et al.*, 2014). Perhaps due to this limited development, single-model MQAPs were a step behind consensus MQAPs in ranking a set of alternative models for CASP targets. This changed lately, as 22 single-model methods took part in the latest edition of CASP and brought an evident increase in performance (Kryshtafovych *et al.*, 2017). Single-model methods are now competitive for many tasks, thanks to the use of improved energy functions and recent developments in machine learning approaches (Moult *et al.*, 2017).

ProQ2 was among the top-ranked methods in CASP11 for the identification of the best model in a dataset, and it was also a good choice for identifying correct local features (Kryshtafovych *et al.*, 2016). The performance of ProQ2 was improved by its newest version ProQ3 in CASP12, which saw single-model methods as the top alternatives for many analyses. The best among these surpassed top CASP11 predictors in selecting the best models out of each decoy dataset (Elofsson *et al.*, 2017). ProQ3, together with single-model methods SVMQA and MESHI-score, have been the top performers overall in CASP12 for this task (Kryshtafovych *et al.*, 2017). In fact, GDT-based measures recognized SVMQA as a top method for identifying good-quality models, regardless of the general approach (Manavalan and Lee, 2017). While distinguishing good from bad models is still better with consensus or quasi-single methods, the best among these use single-model approaches to derive their scores (Elofsson *et al.*, 2017). The benefits of single-model methods are not only recognized by the systematic assessment of CASP. For example, MolProbity, which can evaluate the stereochemical properties of both protein and nucleic acids structures, is a convenient single-model method that has been recommended for the evaluation of side-chain rotamers in X-ray structures by the PDB Validation Task Force team (Read *et al.*, 2011).

Single-model approaches are still behind quasi-single-model methods that, if dataset requirements are met, can often match the performance of consensus-based approaches. When many models are available and show a wide range of accuracy values, and they are prone to be partitioned into good and bad models, quasi-single methods can compete with consensus approaches (Kryshtafovych *et al.*, 2014). In CASP12, estimation of the absolute global correctness of a model (measured as the difference against four reference evaluation scores such as GDT_TS) showed the quasi-single-model approach of ModFOLD6 as the best, followed closely by ProQ3 and a single-model version of MULTICOM (Kryshtafovych *et al.*, 2017). In general, if a reliable set of multiple models is not available for consensus approaches, quasi-single model methods like ModFOLD6 could be a good choice (Kryshtafovych *et al.*, 2017).

It should be noted that the choice of accuracy measure has a crucial impact on the comparative evaluation of the different approaches. It was seen in CASP11 that single-model methods could rank even higher if assessed by measures that consider local similarity, probably because many are built on local descriptions of geometries and energies (Kryshtafovych *et al.*, 2016). Indeed, while GDT_TS shows a clear advantage of consensus and quasi-single based methods in model ranking, other measures like LDDT (based on local distance similarity) and CAD (which compares contact areas) highlight that model accuracy correlates best with the scores from ProQ3 and other single-based methods (Elofsson *et al.*, 2017).

Consensus MQAP

Consensus-based MQAPs usually perform better than single-model methods and up until CASP11, the organizers reported best performances from consensus-based approaches in all categories. ModFOLDclust outperformed all other methods in predicting both global and residue-based quality in CASP8 and was also among the best in CASP9 and CASP10 (Kryshtafovych *et al.*, 2014). QMEANclust was best ranked overall in CASP9 (Kryshtafovych *et al.*, 2011), and other consensus-based methods like MULTICOM, QMEANclust and MetaMQAPclust achieved the top eight spots, with statistically equal performances on a per-target analysis. In CASP11, the top performance of the improved single-model method ProQ2 in selecting the best model available was matched by the clustering-based programs Pcomb and Pcons (Kryshtafovych *et al.*, 2016). Consensus-based methods were still better than other approaches in separating correct and incorrect models in CASP12 (Elofsson *et al.*, 2017). Pcomb showed a statistically better performance than most other methods, followed closely by other consensus-based alternatives. In CASP11 and CASP12, local accuracy was generally better predicted by consensus-based approaches, such as Pcons and ModFOLDclust (Kryshtafovych *et al.*, 2016; Elofsson *et al.*, 2017), which were also significantly better than all other methods in assigning per-residue error estimates. Together with Pcomb, they were the top ranked methods for separating good from bad regions of the models (Kryshtafovych *et al.*, 2017).

The scarcity of non-comparative methods for RNA model quality assessment affects the progress of the field and our understanding of its strengths and limitations. Although no comprehensive analysis has been performed, organizers of the RNA-Puzzles experiments highlighted the advantages of applying a set of metrics that evaluate different structural characteristics for a broader assessment of RNA models (Miao *et al.*, 2017). Following this path, it is expected that integrative consensus-based approaches such as the implemented in the 3DRNA web server could provide the best assessments in the near future.

It is clear from the previous paragraphs that consensus-based methods are generally a good choice for model assessment, but they should not be applied lightly. There are certain caveats associated with their design or performance that may lead to the adoption of other methods better suited for the task at hand. Most consensus-based methods are not intended to assess multi-domain protein models, as they would systematically give higher scores to suboptimal models of the complete structure than to better structures of individual domains. This could become a major issue as modeling methods are now more capable of predicting structures in complex, which are particularly difficult for experimental determination.

An independent assessment by MULTICOM authors showed consensus-based approaches could fail when low-quality models dominate the dataset, especially if many of them are similar to each other (Cao *et al.*, 2014a). In such a scenario it is expected to find a high proportion of bad models, generally within a broad distribution of quality scores, and clustering methods would perform badly since most structures would resemble a low-quality consensus (Moult *et al.*, 2017). The performance of consensus methods (and quasi-single methods too) seems to depend on the existence of best models which scores are much better than the rest (Kryshtafovych *et al.*, 2016). This may all explain why single-model method like SVMQA gave a top performance in CASP12, in which many of the protein targets were difficult to predict (Manavalan and Lee, 2017). Limiting the analysis to hard targets from CASP7 and CASP8 also showed their behaviour was relatively on par with that of single-model methods (Cozzetto *et al.*, 2009).

On the practical side, consensus-based methods would become much slower than single-model methods as the number of models in the dataset grows (Cao *et al.*, 2016a). Although just 20 models were found sufficient for the top performance of consensus-based methods in CASP8 (Cozzetto *et al.*, 2009), the end user may need to generate many more models to achieve a wide spread of quality values (Kryshtafovych *et al.*, 2014). Therefore, consensus-based methods may not be the best available option for researchers that need to assess the global or local quality of a single model to allow its functional analysis.

Discussion

The field of quality assessment of protein and RNA structure models has been making steady progress for more than three decades. Some well-performing MQAPs are now unavailable, like the promising methods MQAPsingle (quasi-single) (Pawlowski *et al.*, 2016) and MetaMQAPclust (consensus-based) (Pawlowski and Bujnicki, 2012), and the clustering methods MUFOLD-QA and MUFOLD-WQA (Zhang *et al.*, 2011) that were among the best in CASP9 (Kryshtafovych *et al.*, 2011). Fortunately, and although with varying levels of success, current MQAPs still comprise several useful methodologies and approaches.

Model assessment is usually performed by comparison against a reference. It is important to recall that experimentally solved structures are also scientific models, based on the interpretation of empirical data, and thus they are not necessarily a faithful representation of reality (Mackay *et al.*, 2017). Quality assessment protocols that rely on comparisons with a reference structure should be taken cautiously. As most similarity measures (like GDT_TS or TM-score) may not have a direct relationship with native-likeness, the best models ranked by such measures might not necessarily resemble real structures.

Typical tools for the analysis of individual structures like Verify3D and Prosa, which have long been used for the evaluation of structures obtained from experimental techniques, have now been outperformed by some of the best modern MQAPs like ModFOLD and ProQ, according to certain analyses (Haas *et al.*, 2017). Both single- or multi-model methods could provide the best assessment of structural models depending on the task at hand, although no method is ideal. Many MQAPs have been developed to distinguish between native and non-native structures, but as mentioned above, structural modeling could be such a hard task that even the best models may fail to describe the native state. Other MQAP have been designed to find the best available models even in these complicated scenarios. The CASP experiments demonstrated that regardless of the approach, not even the best MQAPs could consistently perform well for every protein (Kryshtafovych and Fidelis, 2009). While some methods could succeed in picking the best available structures, they may perform poorly in ranking all models in a decoy set, or vice versa (Kryshtafovych *et al.*, 2014).

As a cautionary note, it should be highlighted that scores derived from MQAPs must behave as a true metric to allow a fair and predictable comparison of alternative models. This has often not been respected, as illustrated by a well-established method such as the Z-score provided by Dali (Adams and Naylor, 2003). Its formulation is such that two independent pairs of identical structures could receive different Z-scores, violating a basic premise of a similarity metric.

Future Directions

The field of model quality assessment is heading to improved and more capable methods. Several metrics based on GDT_TS were already proposed to capture differences beyond C α atoms (Keedy *et al.*, 2009) and we could expect others to integrate independent assessments of both local and global similarity. Some of the new MQAP may revisit typical assets in structural analysis like evolutionary information. It has only been incorporated into MQAPs as site-specific residue conservation data extracted from sequence databases. ConQuass (Kalman and Ben-Tal, 2010), now deprecated, tried to determine the correlation between the

observed amino acids at each site with the model structure. We developed the BeEP server (Palopoli *et al.*, 2013), an MQAP that estimates the correspondence between the substitution pattern simulated under the structural constraints imposed by a protein model and its observed evolutionary history. We expect the explicit use of evolutionary information, as implemented in BeEP, as a clear path towards the advancement of existing programs.

Novel methods should be able to handle special cases of biomolecules like membrane proteins or small RNAs. MQAPs are crucial here since computational models of these structures are usually difficult to obtain with confidence. Unfortunately, these models are still hard to assess by common methods which are not parameterized for their unique characteristics. Advances are being made, as in ProQM-resample (Wallner, 2014) and QMEANBrane (Studer *et al.*, 2014) which allow for the specific assessment of transmembrane protein models.

The last years have seen the development of methods that depart from traditional approaches. The current advancement of deep learning techniques promises a substantial improvement in computational methods for biological research. Model quality assessment programs are not exempt from this trend, with new methods like SMOQ (Cao *et al.*, 2014b), DeepQA (Cao *et al.*, 2016b) and QACon (Cao *et al.*, 2017) already matching state-of-the-art performances. Other modern approaches are also performing well and are likely to be further explored soon. Among these are the graph-based methods implemented in GMQ (Shin *et al.*, 2017), and the addition of information from homologous structures to existing quality scores by machine learning, used by the yet unpublished QMEANDisCo method that performed among the best in the latest CAMEO report (Haas *et al.*, 2017).

As the native state is better described by an ensemble of conformers, an important upcoming challenge is to account for the identification of models integrating this ensemble. They could involve from large conformational changes such as the relative rigid-body movements of large domains (Gerstein and Echols, 2004) to tiny rearrangements as derived from rotations of residues to open, close or enlarge tunnels and cavities (Gora *et al.*, 2013). Discrimination of models with such structural differences should require the development of more sophisticated methods in order to provide functional and reliable 3D models (Palopoli *et al.*, 2016; Monzon *et al.*, 2017). Although some efforts on this direction have been taken, such as with the IDDT score (Mariani *et al.*, 2013) that can take an ensemble of equivalent conformers as reference, the community still needs to widely adopt conformational diversity as a central element in quality evaluation.

Closing Remarks

Current state-of-the-art model quality assessment programs can be useful to assess structural models in real-life study cases. Although consensus-based and quasi-single methods used to perform best than pure single-model MQAPs, and they may still be preferred for local and absolute quality estimations, progress in the latter means they could now be equally or even more effective in ranking models and selecting the best ones. There is still no optimal and universal solution, however, and there's a need for novel protocols for model quality assessment that can achieve a high level of discrimination in complicated scenarios. Within this active field, we expect the strengths and weaknesses shared by successful current programs will lead to improved performances of the upcoming methods.
